CONTRIBUTORS TO VOLUME IX.

A.

ADAMS, Dr. J. Q., Caimel, N. Y.
ALLEN, Dr. NATHAN, Lowell, Mass.

B.

BARKER, Prof. FORDYCE, M.D., New York.
BEARD, Dr. GEO. M., New York.
BENNETT, Dr. W. H., New York.
BIGELOW, Dr. H. R., Hartford, Conn.
BILLINGS, Dr. J. S., Ass't Surgeon U. S. Army.
BIZZELL, Dr. W. D., Gainesville, Alabama.
BLACK, Dr. J. R., Newark, Ohio.
BOWEN, Dr. W. SHAW, Hartford, Conn.
BOZEMAN, Dr. NATHAN, New York.
BRIDGON, Dr. C. K., New York.
BRONSON, Dr. E. B., New York.
BUCK, Dr. A. H., New York.
BUCK, Dr. GURDON, New York.
BULL, Dr. C. S., New York.
BUMSTEAD, Prof. FREEMAN J., New York.
BURNETT, Dr. S. M., Knoxville, Tenn.

C.

CAMPBELL, Dr. W. N., New York.
CARO, Dr. SALVATORE, New York.
CARPENTER, Dr. WESLEY M., New York.
CASTLE, Dr. FREDERIC A., New York.
CHANDLER, Dr. CHAS. F., New York.
CLARK, Prof. ALONZO, M.D., New York.
CLARK, Dr. S. T., Lockport, N. Y.
CLYMER, Dr. MEREDITH, New York.
COLVIN, Dr. D., Clyde, N. Y.
CORSON, Dr. JOHN W., Orange, N. J.
COX, Dr. GEO. M., Springfield, Mo.
CROSBY, Prof. A. B., M.D., New York.
CUTTER, Dr. EPHRAIM, Woburn, Mass.
CUTTER, Dr. GEO. R., New York.

D.

DA COSTA, Prof. J. M., Philadelphia, Pa.
DAVIS, Dr. G. PIERREPONT, Hartford, Conn.
DAWSON, Dr. B. F., New York.
DIMOCK, Dr. SUSAN, Boston, Mass.
DOUGLAS, Dr. A. T., Rondout, N. Y.
DUNGLISON, Dr. R. J., Philadelphia, Pa.
EPCY, Dr. EUGENE, New York.

E.

ELDRIDGE, Dr. STUART, Hakodato, Japan.
ERICHSEN, Prof. JOHN ERIC, E. London.

F.

FLINT, Prof. AUSTIN, M.D., New York.

FRANK, Dr. T. F. Titusville, Pa.
FRYER, Dr. B. E., Surgeon U. S. Army.

G.

GAY, Dr. C. C. F., New York.
GLASGOW, Dr. W. C., St. Louis, Mo.
GODON, Dr. F. W., New York.
GOULEY, Prof. J. W. S., M.D., New York.
GROSS, Prof. S. D., M.D., Philadelphia, Pa.

H.

HALL, Dr. JAMES A., Elmira, N. Y.
HALL, Dr. WILLIAM E., New York.
HAMILTON, Dr. ALLAN McLANE, New York.
HAMILTON, Prof. FRANK H., New York.
HAMMOND, Prof. W. A., M.D., New York.
HENLY, Dr. A. T., Macon Station, Alabama.
HOLDEN, Dr. E., Newark, N. J.
HOWE, Dr. JOSEPH W., New York.
HOUGH, Dr. JOHN STOCKTON, Philadelphia.
HUNTER, Dr. A. S., New York.
HUNTINGTON, Dr. A., New York.

J.

JACOBI, Prof. ABRAM, M.D., New York.
JACOBI, Dr. MARY PUTNAM, New York.
JANEWAY, Prof. E. G., M.D., New York.

K.

KEARNEY, Prof. J. H., M.D., Cincinnati, Ohio.
KELSEY, Dr. CHARLES, New York.
KEYES, Prof. E. L., M.D., New York.
KIP, Dr. ISAAC L., New York.
KNAPP, Dr. HERMANN, New York.
KRACKOWIZER, Dr. Ernst, New York.

L.

LAUDERDALE, Dr. J. V., Ass't Surgeon U. S. Army.
LEAMING, Prof. JAMES R., M.D., New York.
LEALE, Dr. CHARLES A., New York.
LEFFERTS, Dr. GEORGE M., New York.
LENTE, Dr. FREDERICK D., Cold Spring, N. Y.
LINCOLN, Dr. R. P., New York.
LOOMIS, Prof. A. L., M.D., New York.
LORING, Dr. E. G., New York.

M.

MARKHAM, Dr. H. C., Winthrop, Iowa.
MASON, Prof. ERSKINE, M.D., New York.
MATHEWSON, Dr. A., Brooklyn, N. Y.
MATTISON, Dr. J. B., Chester, N. J.
MAURY, Dr. T. F., Philadelphia, Pa.
MITCHELL, Dr. GEORGE H., House-Surgeon St. Peter's Hospital, London.
MOORE, Prof. E. M., M.D., Rochester, N. Y.

MORSE, Dr. W. H., New York.
 MUNSON, Dr. W. W., Otisco, N. Y.
 MURRAY, Dr. ALEXANDER, New York.

N.

NEWMAN, Dr. ROBERT, New York.
 NOYES, Prof. HENRY D., M.D., New York.

O.

OLKSON, Dr. C. W., Bloomingdale, Ill.

P.

PARKER, Dr. THEODORE, New York.
 PEUGNET, Dr. EUGENE, Fordham, N. Y.
 PIFFARD, Dr. HENRY G., New York.
 PINKHAM, Dr. H. G., Lynn, Mass.
 POST, Prof. ALFRED C., M.D., New York.
 POST, Prof. GEO. E., M.D., Beirut, Syria.
 PROUT, Dr. J. S., Brooklyn, N. Y.

R.

ROBINSON, Dr. BEVERLEY, New York.
 ROCKWELL, Dr. A. D., New York.
 RODMAN, Dr. W. B., Frankfort, Ky.
 ROSE, Dr. A., New York.
 RUMBOLD, Dr. T. F., St. Louis, Mo.
 RUSSEL, Dr. CHAS. P., New York.

S.

SALISBURY, Dr. A. H., Minneapolis, Minn.
 SANDS, Prof. HENRY B., M.D., New York.
 SATTERTHWAITE, Dr. T. E., New York.
 SAYRE, Prof. LEWIS A., M.D., New York.
 SCHWEIG, Dr. GEO. M., New York.
 SEGUIN, Dr. E. C., New York.
 SHEFFIELD, Dr. D. A., New York.
 SIMON, Prof. GUSTAV, Heidelberg.
 SIMMONS, Dr. D. B., Yokohama, Japan.
 SKENE, Prof. A. J. C., Brooklyn, L. I.
 SMITH, Dr. A. H., New York.
 SMITH, Dr. GEO. C., Rondout, N. Y.
 SMITH, Dr. J. LEWIS, New York.
 SPEIR, Dr. S. FLEET, Brooklyn, N. Y.
 STURGIS, Dr. F. R., New York.

T.

THOMAS, Prof. T. GAILLARD, M.D., New York.
 THOMSON, Dr. GEO., New York.

V.

VAN BUREN, Prof. WILLIAM H., M.D., New York.
 VAN WYCK, Dr. R. C., Culpepper Co., Va.

W.

WALES, Dr. PHILIP S., U. S. Navy.
 WARD, Prof. SAM'L B., M.D., New York.
 WARNER, Dr. L. C., New York.
 WATERMAN, Dr. S., New York.
 WEIR, Dr. ROB'T F., New York.
 WHITALL, Dr. S., New York.
 WILLIAMSON, Dr. J., Ottumwa, Iowa.
 WOODWARD, Dr. J. J., Ass't Surgeon, U. S. Army.

*Societies and Institutions from which Reports have been
 furnished.*

AMERICAN MEDICAL ASSOCIATION.
 BELLEVUE HOSPITAL, New York.
 BELLEVUE HOSPITAL MEDICAL COLLEGE, New York.
 BROOKLYN CITY HOSPITAL, Brooklyn, N. Y.

INDEX.

A.

ABDOMEN, gunshot wound of, 73; diagnosis of enlargement of, 396; pain and cramps in, as symptoms, 427.

Acne, treatment of, 235, 424.

Adams, Dr. J. Q., fract. temporal bone, 288.

Address on practical medicine, 312.

Adhesive plaster, first employment of, 157.

Agassiz, Prof. Louis J. R., death of, 24.

Age, ameliorating the effects of, 446; relation of, to medical work, 293.

Agent, an honest (life insurance) necessary, 168.

Air-passages, abnormal conditions of, 477.

Albumen, how to treat with nitric acid, 546.

Alcohol, influence of, on heart, 403; and the profession, 357.

Allen, Dr. Nathan, law of longevity, 108; appendix veriformis, 579.

American Medical Association, 70, 216, 302, 305, 323, 380.

American Public Health Association, 640.

Ammonæmia, new views on, 370.

Amputations, periosteal, flaps in, 572.

Amyl colloid in shingles, 176.

Amyl, valerianate of, 402.

Anæsthetics, unnatural position of head, cause of death from, 403.

Aneurism; treated by horse-hairs, 376; lecture on, 561, thoracic, case of, 653.

Angina, treatment of, 120, 147.

Animal vaccination, remarks on, 22.

Anstie, Dr. Francis Edmund, death of, 551.

Azus, fissure of, 585.

Apollinaris water, 292.

Apomorphia as an expectorant, 540.

Army medical staff rank, 13, 38, 47, 70, 72, 79, 125, 130, 204, 311, 373.

Army news, 24, 45, 79, 135, 192, 215, 247, 270, 303, 328, 381, 471, 416, 439, 496, 526, 550, 607, 663.

Arsenical poisoning from green carpet, 68; from wall-papers, 528.

Arteries, ligation of, 88.

Aspergillus in external auditory canal, 86.

Aspirator, use of in retention, 117, 343; an inappropn. 438.

Asthma, spasmodic, treatment of, 507.

Atheroma of cerebral vessels, 302.

Auditory canal, parasitic growth in the, 344.

Aveling's apparatus for transfusion, 190.

B.

Bacteria and disease, 121.

Barker, Dr. Fordyce, on transfusion, 187; review of work by, 294; age in relation to child-bearing, 658.

Basham's mixture, formula for, 546.

Baylis, Dr., death of, 191.

Bead, inhalation of, 212.

Beard, Dr. Geo. M., central galvanization, 172; hemiplegia, 265; uses of electricity, 354.

Beef, raw, in irritable stomach, 143.

Beer, poisoning by colchicum in, 369.

Bellevue Hospital, changes in, 439, 526; reports from, 9, 64, 88, 119, 141, 176, 235, 345, 368, 400, 426.

Bellevue Hospital Medical College, 158.

Bennett, Dr. W. H., on superior air-passages, 477.

Bichloride of methylene, merits of, 252.

Bigelow, Dr. H. R., acute insanity, 455.

Biliary calculi, case of, 408.

Biliary ducts, cancer of, 40.

Bizzell, Dr. W. D., aspergillus, 86.

Black, Dr. J. R., hygiene and therapeutics, 133; longevity, 497.

Bladder, abscess of, 186; extraction of foreign bodies from, 117, 468; aspiration of, 234; removal of tumor of, 483; exploration of female, by finger, 604; catheter for irrigating the, 627; rupture of, from kick, 635.

Blake, Dr., on sanguinolent tumor, 42.

Blennorrhagia, treatment of, 260.

Blindness, causes of, 599.

Blood, action of iodid. potas. on, 528; overlooked source of supply of, 346; stains of, 513; hypodermic injection of, 458; spectroscopic analysis of, 531.

Boils, treatment of, 428.

Bones, to increase the growth of, 36.

Bowen, Dr. W. Shaw, parasitic growth in auditory canal, 344.

Boydland, Dr. G. H., notice of work by, 15.

Bozeman, Dr. N., letter from, 604.

Brain, destruction of one of the hemispheres of the, 260; staining of, for microscope, 292; experiments upon the, 346; tumor of, 651.

Brain-workers, longevity of, 605.

Breast, adenoma of, 635.

Briddon, Dr. C. K., cancerous breast, 213; cancer omentum, 411.

Bright's disease, treatment of, 65, 119, 546, 574.

Brodie, Dr. W., address by, 305.

Bromine and its compounds, 238.

Bronchial gland, rupture of, 572; enlarged, and wheezing respiration, 636.

Bronchial tube, rupture of, during coughing, 29; fibrinous casts of, 41, 78.

Brooklyn City Hospital Reports, 145, 345, 634.

Brown, Dr. Harvey E., notice of work by, 15.

Buck, Dr. A. H., causes of 1,000 deaths, 49; mortality of phthisis, 105.

Buck, Dr. Gurdon, cicatrices from burns, 473.

Buffalo General Hospital Reports, 662.

Bull, Dr. C. S., traumatic paralysis of rectus and inferior oblique muscles, 366.

Bull, Dr. R. W., death of, 608.

Bumstead, Dr. F. J., tunneled urethral instruments, 45; antiquity of syphilis, 244.

Bunion, resection as a remedy for, 200.

Burnett, Dr. S. M., nervous deafness, 420.

Burns, treatment of, 234; contractions from, 473.

C.

Calabar bean in tetanus, 536.

Calculi, cases of, from Beirut, 186.

Calculus, expulsion of, 12; case of salivary, 510.

Campbell, Dr. W. N., lumbar hernia, 142.

Cancer, treatment of, 197, 213, 280, 290.

Cardiac sedative, quinine as, 285.

Caro, Dr. S., swallowing a shawl-pin, 214, 242, 285.

Carpenter, Dr. Wesley M., hospital reports of, 9, 64, 88, 119, 143, 176, 234, 296, 345, 368, 400, 426.

Carter, Dr. R. B., waste of life, 333, 386.

Castle, Dr. F. A., puerperal fever in Bellevue Hospital, 461.

Catarrh, bronchial, treatment of, 459.

Catheter, self-retaining, 215.

Catheterism, peculiar, 409.

- Cavities, pulmonary, hypodermic injection of, 578.
 Central galvanization compared with other methods of using electricity, 172.
 Cerebral hemorrhage and apoplexy of kidneys, 516.
 Cerebral hemisphere, physiology of, 376.
 Cerebro-spinal meningitis, cases of, 60, 292.
 Cervix uteri, polypoid elongation of, 509.
 Circumcision, notice of work on, 431.
 Charity Hospital reports, 143.
 Chancre, treatment of, 568.
 Chandler, Dr. Chas. F., mortality of New York, 223.
 Child-bearing, age in relation to, 657.
 Children, diseases of, notice of work on, 325.
 China, physiology in, 384.
 Chinese and Japanese, physical types compared, 163.
 Chloral in cancer, 257; treatment of poisoning by, 328; combined administration of, with morphia and atropia, 637.
 Chlorate potash, topical use of, 259.
 Chloroform, death from, 248, 542.
 Cholera discharges, action upon animals, 35; transmission of, 95.
 Cholesterol, injection of, 259.
 Chromic acid and glycerine, danger of mixing, 347.
 Chronic diarrhoea, treatment of, 345.
 Clark, Dr. S. T., epidemic colitis, 61.
 Cleft palate, new operation for, 92, 402.
 Climate, question of, in phthisis, 297.
 Clinical medicine, Trousseau's review of, 14.
 Club-foot, clinical lecture on, 361; treatment of, 401.
 Cod-liver oil, tasteless, 234; use of, 299.
 Code of ethics; revision of, 309; remarks on the, 573.
 Coitis, epidemic, an unusual type of, 61.
 College of Physicians and Surgeons, commencement, 158.
 Colloid cancer of gall-bladder, 301.
 Colotomy, 299.
 Colvin, Dr. D., on life insurance agents, 168.
 Conjunctiva, cancer of, 243.
 Confederate surgeons, convention of, 304.
 Consultations in the country, 181.
 Consumption, mortality of, 329, 445; notice of work on, 407; treatment of, 546.
 Contagious diseases, reports on, 80.
 Corpus luteum, age of, 211.
 Corpus callosum, absence of, 664.
 Corson, Dr. John W., general treatment of pleurisy, 623.
 Coryza, new treatment for, 8; fluid discharges of, 402.
 Cough of phthisis, treatment of, 297.
 Cox, Dr. Geo. M., insurance examiners, 277.
 Cremation, 248, 287.
 Crosby, Dr. A. B., perforation of mastoid cells, 20; talipes varus, 18.
 Croton chloral-hydrate in insanity, 455.
 "Croton Oil Paint" in pleurisy, 622.
 Croupous pneumonia, statistics of, 370.
 Cruveilhier, Dr. J., death of, 191.
 Cutter, Dr. E., sore nipples, 180.
 Cystitis, local treatment in females, 512.
- D.
- Da Costa, Dr. J. M., acute articular rheumatism, 481; clinical cases, 337.
 Dalton, Dr. J. C., on spectroscopy, 599.
 Danish treatment of joint affections, 2.
 Davis, Dr. G. Pierrepont, vertical luxation of patella, 627.
 Davis, Dr. N. S., address on medicine, 312.
 Dawson, Dr. B. F., bichlor. methylene, 252; on ovariotomy, 638.
 Deafness, nervous, origin of some forms of, 420.
 Deaths, 1,000, inquiry into causes of, 49.
 Deformities, inheritance of, 527.
 Delafield, Dr. F., cancer of stomach, 579; dilatation of heart, 652.
 Diarrhoea of phthisis, 577.
 Diagnosis, a question of, 208.
 Dictionary, medical, notice of, 264.
 Digestion and absorption in the large intestine, 459.
 Digitalis, hypodermics of, 119; stupes of, as diuretics, 400.
 Dimock, Dr. Susan, rudimentary uterus, 423; recto-vaginal fistula, 458.
 Diphtheria, treatment of, 144, 183, 260, 347, 577.
 Diseases of women, notice of work on, 324.
 Dissection, legalized, 191.
 Doremus, Dr. R. O., on poisoning, 602.
 Douglas, Dr. A. T., novel method of extracting a glass tube from the bladder, 117.
 Drainage and sewerage, Dr. M. Morris on, 129.
 Driking-water, contaminated, 517.
 Dupuy, Dr. E., physiology of cerebral hemispheres, 376.
 Dust, influence of, on health, 273, 442, 556, 369; 669.
 Dyscutery, chronic, treatment of, 9, 12, 537.
 Dyspepsia, remarks on, 297, 422, 483.
- E.
- Ear, fibromata of, 636.
 Early maternity, case of, 536.
 Earth as a surgical dressing, 141, 547.
 Eczema, treatment of, 350.
 Elastic ligature, 118.
 Elastic thread, 91.
 Elbow, excision of, 213; luxation backwards, 207.
 Eldridge, Dr. Stuart, catheter for irrigating the bladder, 627.
 Electrical force, resistance of body to, 375.
 Electricity, uses of, 554, 601; notice of work on, 430.
 Electro-cantery, notice of work on, 295.
 Electrolysis in stricture, 100; extraordinary case of, 384.
 Electrolyzing the base, 99.
 Embolism, multiple, etc., 495, 542.
 Emetics, contribution to the study of, 146.
 Emotional insanity, 358.
 Employments, health of different, 609.
 Epilepsy, albuminuria as a symptom of, 347; treatment of, 403, 549.
 Epiphyseal fracture of the head of the humerus, 353.
 Episclear melanotic sarcoma, 23.
 Episcopal Hospital reports, 592.
 Epistaxis, sero-albuminous, 147; treatment of, 437.
 Epithelioma of cervix uteri, 396.
 Ergot poisoning, a case of, 471.
 Ergotine, hypodermic injection of, 260.
 Erichsen, J. E., on anchylosis, 599.
 Esmarch's bloodless operations, 59, 133, 146, 257, 380, 592, 655.
 Ether, administration of, 9.
 Exchanges, articles on, 15, 75, 123, 147, 203, 245, 267, 296, 347, 372, 472, 521, 594.
 Extension by adhesive plaster, first employment of, 157.
- F.
- Fallopian abscess, 579.
 Faradic baths, uses of, 647.
 Fees, question of, 336.
 Femoral artery, ligation of, 321.
 Femoral hernia, unreduced, 635.
 Fibrous anchylosis, lecture on, 449.
 Finnell, Dr. T. C., corpus luteum, 211; cancer of liver, 650.
 Fiset, Dr. G. Morrison, puerperal convulsions, 342.
 Fisher, Dr. A. R., massage on joint affections, 2.
 Fistula in ano, lecture on, 505.
 Flatus, a pill for, 234.
 Flint, Dr. A., fibrinous casts of bronchial tubes, 41.
 Fetus, influence of chloroform on, 460.
 Food, poisonous adulteration of, 471.
 Forearm, dislocation, treatment of, 341.
 Fractures, different plans of treating, 10, 101, 143, 145, 235, 353, 363, 400, 414, 576, 593.
 Fragilitas ossium, 404.

Frank, Dr. T. F., electrolysis in stricture, 62.
 Fryer, Dr. B. E., transfusion, 201.
 Furuncular affection, sulphides in, 257.

G.

Gall-bladder, cancer of, 407; rupture of, from fall, 578.
 Galvano-therapeutics, notice of work on, 296.
 Gardner, Dr. John, on old age, 446.
 Garretson, Dr. J. E., notice of work by, 15.
 Gastritis, subacute, heat of, 9.
 Gastrotomy for uterine tumors, 122.
 Gay, Dr. C. C. F., surgical cases, 662.
 Gelatine, medicated, 147.
 Glasgow, Dr. W. C., on residual air, 63.
 Glioma retinae, 209, 494.
 Glioma-sarcoma of upper thigh, 185.
 Goitre, exophthalmic, treatment of, 506.
 Godon, Dr. F. W. fuller's earth as a dressing, 141.
 Gonorrhoea, treatment of, 234.
 Gonorrhoeal epididymitis, structural changes in, 347.
 Gouley, Dr. J. W. S., tunnelled urethral instruments, 90.
 Gout, treatment of, 9.
 Graafian vesicle, retrograde metamorphosis of, 539.
 Grape cure, the, 527.
 Great toe, resection for abduction of, 200.
 Griffith's formulary, review of, 206.
 Griscom, Dr. John H., death of, 271, 304.
 Gross, Dr. S. D., cases from clinic of, 587.

H.

Hæmoptysis, 193, 298, 577.
 Hæmorrhoids, lecture on, 293, 417.
 Hairy men, 48.
 Hall, Dr. James A., aspiration for retention, 343.
 Hall, Dr. W. E., chronic pachymeningitis, 19; tumor of the abdomen, 211.
 Hallux valgus, resection for, 200.
 Hamilton, Dr. F. H., separation of upper epiphysis of humerus, 231; warm water in surgery, 249.
 Hammond, Dr. W. A., effects of alcohol, 236; on the rights of independent criticism, 488.
 Hand, back of, as thermometer, 119.
 Hay-fever, experimental observation on, 424.
 Heart, fatty degeneration of, in women dying of syncope after delivery, 122; disease of, from overwork, 260; disease and œdema of left upper extremity, 292; influence of tobacco and alcohol on, 403; dilatation of, 652.
 Hematometra, case of, 527.
 Hemiplegia, treatment of, 265; curious cases of, 345.
 Henly, Dr. A. T., case of stabbing, 423.
 Hernia, reduction of internal, 12; treatment of, without opening the sac, 137; incarcerated, case of, 494.
 Heywood Smith's scissors, 215.
 Hip, dislocation of, in woman aged 73; excision of, 432.
 Homeopathy in England, 528.
 Holden, Dr. E., laryngeal pathology, 287.
 Holston, Dr., health of, 304.
 Hospital for the Ruptured and Crippled, report from, 401.
 Hospital appointments, 69, 94, 183, 429.
 Howard, Dr. E. L., emotional insanity, 358.
 Howe, Dr. Joseph W., transfusion, 171.

Original Lectures.

ON VARIOUS FORMS OF DISEASE OF THE ŒSOPHAGUS.

THE ABSTRACT OF A LECTURE DELIVERED BY

MORELL MACKENZIE, M.D., LONDON.

PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE THROAT,
SENIOR ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL,
ETC., AT THE LONDON HOSPITAL, JULY 25, 1873.

(Reported specially for THE MEDICAL RECORD.)

By BEVERLEY ROBINSON, M.D.

(UNIV. OF PARIS), PHYSICIAN TO THE NEW YORK DISPENSARY, ETC.

If we refer to our classical authors, such as Reynolds and Aitken, we find little on the subject which shall form the substance of our lecture. In some works on medicine, diseases of the œsophagus are not even mentioned. This is attributable to the fact that morbid affections of this organ are rare. They are not caused by cold or chill. In point of fact, there is no such affection as catarrh of the œsophagus.

The peculiarity of the œsophagus is its epithelium, which is extremely thick, and its mucous membrane—less vascular than any other of the economy. This explains why it is less prone to disease.

Malignant disease of the œsophagus occurs late in life. It is extremely rare under 30 years of age, and we encounter it most frequently between the ages of 50 and 65.

Nine-tenths of the cases of malignant disease of the œsophagus are of the nature of epithelioma. Scirrhus is exceptionally met with.

But little pain may be present, even where there is serious lesion. This depends upon the depth of the epithelial covering and the diminished supply of blood (already noted) in the mucous coat. In all cases of this kind, we have abundant frothy expectoration, and when this does not exist, we can give a more favorable prognosis, even though the stricture be evident, as it is then more than probably due to other than a carcinomatous affection. Syphilitic ulceration of the œsophagus is often confounded with malignant disease.

Iodide of potash should be the touchstone by which the accuracy of our diagnosis is rendered apparent; for if the patient be suffering from a manifestation of the syphilitic diathesis, a rapid cure is frequently produced by its administration.

The anatomical relations of the œsophagus are as follows: It begins on a level with the fifth cervical vertebra, is directed in its downward course from this point, at first towards the left, then to the right, and, arrived at the ninth dorsal vertebra, enters the stomach. In the bougies now employed by us for sounding this passage, the stem is made of whalebone, terminated at one extremity by an ivory ball or bulb of oval shape.

These bulbs are graduated of different sizes, and are all perforated in a similar manner, so as to allow of their being screwed on or off the same stem, according to the particular size which is required.

The ordinary gutta-percha bougie is objectionable, because it cracks readily with the different changes of the ambient atmospheric medium. Besides, with this latter bougie we are liable to employ more force than we should, as it is not so elastic and yielding as the one made of whalebone.

Before passing a bougie in the œsophagus, it is customary to smear it with oil. This is unnecessary, as water amply suffices to render its passage easy and painless. It is important, in order to avoid *certainly* a false passage, to keep the bougie in the middle line of the throat, during the time of its introduction. This may readily be accomplished by placing the index-finger of the left hand at the posterior wall of the pharynx, and using it as a guide for the bougie. At the same time a steady and gentle pressure must be exercised, and the operation is frequently rendered relatively simple.

The auscultation of the œsophagus is comparatively a *nouveauté*, and was proposed for the first time by Hamburger, a German. In listening with the stethoscope, we must pay attention to the curves made by the œsophagus, and this instrument is to be applied especially to the left side of the vertebral column. The ordinary deglutition sound is that of a spindle-shaped body being caught by a ring. We can almost always detect this sound when a liquid is swallowed by a healthy patient. In the dorsal region, about the middle of the scapula, we hear the spindle-shaped sound or click with greatest intensity. In cases where, instead of the sound of a gliding body, we hear simple gurgling, it is a proof that the patient has a long and extensive stricture and considerable thickening of the lining membrane of the œsophagus. The gurgling sound is more feeble below the stricture than on a level with it. It is injurious for patients suffering from disease of the œsophagus to take stimulants, or anything in the way of nutriment which is of an irritating nature. Meat and bread should be strictly forbidden. We may and ought, however, to give plenty of milk and sufficient quantities of mild, invigorating substances, such as arrow-root or soft-boiled eggs. In malignant disease little can be done beyond the dietary measures indicated, and the use of certain palliative drugs. Benefit is often derived from the exhibition of small doses of opiates. Gastrotomy in these cases has never been successful, and the operation has been abandoned by the surgeons who were at one time advocates of it.

After syphilitic ulceration we have contraction, and we frequently get good results by passing bougies. In using them there is always some attendant risk, however, and in attempts made, the end of the instrument may find its way across the walls of the œsophagus into the posterior mediastinum. Considering this possibility, and too fearful of its occurrence, some practitioners decline to employ bougies at all. Mackenzie advises *not* to pass bougies when there is ulcera-

tion, inasmuch as fear of a false passage is then legitimate, and we cannot in this way render any possible service. Besides, if an accident to the patient should occur, much useless discredit is brought upon the attending physician; as in those cases on record where death was the unhappy consequence within 24 hours after a too daring effort to conquer an obstacle. In those cases where the œsophagus is *contracted* and *ulcerated*, the diagnosis is generally rendered certain by a frothy expectoration. At times it may be advantageous to make use of the conical or tapered bougie. If, however, any obstruction is encountered, the bougie must be withdrawn immediately, and under no circumstances must we endeavor to overcome it, even by a moderate exertion of force. As a rule, it is more prudent to pass only one bougie at a sitting, and more than one case might be cited where the non-observance of this law has too manifestly resulted in the production of a false passage.

Cases of paralysis of the œsophagus are occasionally met with, and more particularly amongst quite old people. This paralysis consists essentially in a loss of power in the constrictor muscles. The patients suffering from this disease generally enjoy tolerably good health in other respects. They experience most difficulty in swallowing solids. This trouble of function is readily explained by our knowledge of physiology, *i.e.*, deglutition is not a simple mechanical act, it is something more, and in order that it may be properly performed, the muscles of the pharynx must contract and seize the alimentary bolus. In the cases under consideration, great benefit is derived from faradization of the inactive muscles, and happily their normal action is oftentimes restored in part. Unfortunately, however, relapses are frequent, and after a time the disease may and does recur in a form as exaggerated as when the electrical treatment was first experimented.

In hysterical patients we have what is known as hysterical and spasmodical dysphagia.

The treatment here consists in general constitutional measures. At the same time the patient must be subjected to moral influences, and special care should be taken, so that attention may not be directed, at least visibly, to their real disease. Apparent disease of the œsophagus is often caused by the pressure of a tumor situated in the anterior mediastinum. The lymphatic glands, increased in size, may also press upon the œsophagus and push it to one side. We then find with the stethoscope a difference of position in the gurgling sound. By compression of one of the recurrent nerves, difficulty of swallowing is produced. This symptom frequently occurs in patients who have difficulty in approaching the vocal cords.

During deglutition, as we are aware, the vocal cords should normally approximate; and if they do not, liquids often pass into the larynx and cause cough and transient symptoms of asphyxia.

MARYLAND EPIDEMIOLOGICAL SOCIETY.—At the last monthly meeting of this society Professor Nathan R. Smith was unanimously elected a member. The officers nominated by the Executive Committee for the ensuing year were: For Honorary President, Prof. Nathan R. Smith; President, Dr. James A. Stewart (Health Commissioner); Vice-President, Dr. George W. Benson; Recording Secretary, Dr. A. H. Saxton; Treasurer, Dr. Thomas B. Evans; Executive Committee, Dr. J. J. Caldwell, Dr. J. Harvey Hill, and Dr. J. E. Atkinson.

Original Communications.

THE TREATMENT OF JOINT-AFFECTIONS BY MASSAGE.

ARRANGED BY

WM. R. FISHER, M.D.,

AFTER ORAL TRANSLATIONS FROM THE DANISH,

By GEO. R. CUTTER, M.D.

My friend Dr. Geo. R. Cutter has had the kindness to give me an oral translation of a series of six papers (seventy-one pages) relating to the treatment of various forms of disease by massage, which have appeared within the last twelve months in the *Norsk Magazin for Lægevidenskaben*; and, from notes which were taken by me during the reading of these articles, I have prepared the following abstract of the views which are expressed in three of them, upon the treatment by massage of a single class of diseases: namely, those of the joints. In making the selections I have intentionally excluded all matters which are extraneous to this topic; but, at the same time, I have endeavored to avoid the omission of anything that is essential to a clear statement and a correct understanding of the subject, and I have taken special care to follow the arrangement of the original, as far as possible, and to adhere to the technical nomenclature of the authors.

The word massage (Arab. *mass*; Gr. *μάσσω*: to knead) has been adopted by these Danish writers from the French, and signifies the use of such passive manipulations as rubbing, kneading, percussing, and rolling of the soft parts. Some of the authors extend its meaning so as to include passive movements of the joints; while others restrict it to manipulations which can be given with the fingers, and use the term *effleurage* to designate hand-rubbing. With such refinements, however, we have nothing to do at present. The reader may understand the word massage, whenever it occurs in this paper, to mean passive manipulations with the fingers or hands; when movements of the joints are spoken of, the term passive movement will be employed.

The attention of the profession in Denmark has been especially directed towards the subject of massage by the wide-spreading reputation of Dr. Mezger, a Dutch physician now practising at Bonn, who has recently achieved an increased celebrity by a successful employment of this means in the treatment of the Danish Crown-Prince. The above mentioned papers all relate to Mezger's method, as it is called; and since the reputation of this physician is chiefly dependent upon his success in the treatment of joint-affections (although he extends his method to a variety of other complaints), this abstract is confined to the consideration of that class of diseases. It should be borne in mind that the American method of treating joint inflammations by extension and counter-extension, without preventing locomotion, is rarely used anywhere in Europe, and in Denmark and the Scandinavian countries has probably scarcely been heard of; so that the objections which are hereafter, in the course of this paper, to be made against "the usual methods of treatment," should be understood to refer, for the most part, to the use of counter-irritants and the plaster-of-Paris bandage.

It is not likely that many will be willing to accept in full the favorable opinions which some of the Dan-

ish physicians express with reference to an exclusive treatment of diseases of the joints by manipulations and movements; yet some may find, in the arguments which are brought forward in support of the mechanical method, and in the illustrations of its practical effects, sufficient evidence to awaken an inquiry into the advisability of diminishing, to some extent at least, that exclusive use of retentive apparatus, to prevent all motion between the joint-surfaces, which is now too common. A conservatism, which depends in great measure upon the force of habit and the weight of foreign authorities, still keeps too many of our own surgeons from practically recognizing, in the treatment of joint-affections, the importance of securing moderate motion with adequate protection against injury—a therapeutic principle which American orthopedists have the honor to have discovered and elaborated.

The theoretical basis for a treatment of joint-diseases, and especially of synovitis, by massage, is well stated in a paper by Candidate of Medicine, F. Kier (*Norsk Mag. for Læg.*, 3d ser., 3d vol., No. 4). He begins by quoting Ilueter's remarks, to the effect that diseases of the articulations often end in death; sometimes in incomplete recovery; very seldom in perfect cure; and that attention should be directed towards the improvement of our means of treating, not only the primary attacks, but especially the effects of these diseases. He then proceeds to introduce the subject of the treatment of affections of the joints by massage, on the ground that it behooves us to try thoroughly every new method which promises in any way to reduce the above-mentioned deplorable results. Massage, however, is not properly speaking a new remedy, for it has been made use of from time immemorial in various nations and in all ages; but he claims that, as a special means of treatment, it may now be ranked much higher among the list of therapeutic agents than has hitherto been possible; and to Dr. Mezger he accords special credit for having been prominent in the development of its curative powers, and in its elevation in the estimation of the profession.

Dr. Mezger employs massage in treating both acute and chronic synovitis in the articulations of the extremities. In the case of the hip-joint, however, he does not use it; partly on account of the deep situation and anatomical relations of this articulation, and partly from the fact that its inflammations often depend upon primary osteitis. He divides his frictions into two classes: the first, passing from side to side (horizontal frictions); the second, passing from below upwards in the line of the limb (vertical frictions). The applications vary in force according to the effect which he desires to produce, and are made, not only upon the joint itself, but also upon the adjacent unaffected tissues. By means of the horizontal frictions the skin is moved about over the fasciæ and ligaments, and the superficial vessels are acted upon, partly by the direct application of mechanical force, and partly by the indirect influence of the vaso-motor nerves. The circulation of the blood is thereby increased; and where there is a tendency to venous stagnation, the bluish color is removed, and the skin assumes its natural appearance. The vertical frictions are made in the direction of the circulation of fluid in the venous and lymphatic vessels, and promote the flow within them. By a combination of these two methods of manipulation—the one stimulating the action, and the other propelling the contents of the blood-vessels and lymphatics—absorption is necessarily increased. Still further, when there are deposits or effusions of blood in the soft parts, the use

of frictions may bring about slight changes in their position, and tend to disperse them, by breaking them up and rendering them more readily absorbable. Massage, therefore, is a powerful agent in producing the absorption of effused materials; acting both by preparing them for removal, and also by promoting the proper function of the lymphatic vessels. It is true that moderate compression will likewise promote absorption by the lymphatics. But compression acts upon the subcutaneous veins, and gives rise to oedema of the parts below the point of its application; whereas, by the use of massage, not only is there no obstruction offered to the venous flow, but, on the contrary, the circulation is greatly promoted. For these reasons massage can be used with great confidence in the treatment of synovitis.

In acute and chronic synovitis serosa the vertical frictions are more applicable than the horizontal. In addition to the effusion within the membrane of the joint, we have to deal with an infiltration and hyperæmia of the synovial and peri-synovial tissues. The vascular network which surrounds the joint is dilated, and the circulation in the blood and lymphatic vessels is correspondingly sluggish. By the use of massage, as we have seen, the absorption of the effusion can be hastened, and the retarded circulation rendered free, or, in other words, the disease can be cured; while, at the same time, a moderate use of the affected joint is not denied to the patient.

According to Mezger, the average time which is required for the treatment of an acute synovitis by his method is two weeks, and for a chronic case six weeks. Candidate Kier does not think that a simple hydrarthrosis can be cured any more rapidly by rest, position, and counter-irritation than by massage, but is of the opinion that a cure by the former methods is much more likely to be followed by a relapse than where the mechanical treatment has been resorted to. As to the cost of the latter, an objection which many have raised against it, he argues that, since it does not compel a patient to give up his occupation during its employment, it may, in many instances, be more economical than the plans of treatment which are in more common use.

The hyperplastic forms of synovitis require a somewhat more complicated treatment. [The author, in a foot-note, excludes from consideration all cases which have advanced to suppuration.] Both the horizontal and the vertical frictions are to be employed, and usually strong pressure is required, especially over those points where the peri-synovial tissue is felt to be much thickened. The more acute the inflammatory process, the softer should be the pressure, as a general rule; because, if it be made too roughly, it might excite inflammation and pain, and also because forcible pressure is not necessary for the removal of the disease. This rule holds good likewise when a chronic synovitis takes on itself the subacute condition.

Synovitis hyperplastica presents a hyperplasia of the areolar tissue in the synovial membrane and the peri-synovial tissues, together with a more or less plentiful serous exudation. At the same time there is a development, in greater or less abundance, of newly formed vessels, and perhaps also of new formations in the system of canals from which the lymphatics take their origin. The combined use of both varieties of frictions in such cases produces in the first place an effect upon the peri-articular tissues, and diminishes the tumefaction which there exists. Not infrequently this alone is sufficient to cause the subsidence of the inflammatory process in the synovial membrane, and the disease is cured. But usually a more protracted

course of treatment is necessary. The skin begins to assume its natural hue; the dilated veins, which have been showing themselves through it, disappear from sight; and, first in one spot, then in several, and finally over the whole surface, the swelling subsides, and the peri-synovial tissues are felt to be restored to their normal state, although occasionally still remaining somewhat thickened. This restoration shows itself at different points with varying rapidity. In the knee, for example, the infiltrated tissues over the external alar ligament are the slowest to recover.

The process of cure very likely takes the following course: The serous effusion is first absorbed, after the manner that has previously been described. The newly formed areolar tissue becomes cicatricial, thickening the peri-synovial tissues and the synovial membrane, and, by its contraction, diminishing the calibre (*lumen*) of the newly formed vessels, so that their walls contract and atrophy. The dilated vessels, under the manipulations, become more or less completely emptied, and their walls are thus enabled to contract by their own elasticity. At first, however, they dilate again between the applications of the treatment, but gradually they more and more regain their proper tonicity. Still further, by means of the stronger frictions, the thinner vessels are ruptured, and blood is effused into the cellular tissue, where it is absorbed; and then the ruptured vessels atrophy. In synovitis granulosa such extravasations often occur during a treatment by massage; but when care is exercised to prevent the effusion of blood from becoming excessive, no bad results ever follow.

In synovitis pannosa, as is well known, the cartilages of the joint present a vascular development whose vessels chiefly originate from, and stand in connection with, the newly formed vessels in that portion of the articular tissues which is transitional between the synovial membrane and the joint-surfaces. If we can cause the last-named vessels to atrophy, we may reasonably expect the vessels on the joint-surfaces, with which they are directly connected, to atrophy also; and therefore, in employing massage in such cases of joint-disease, it is of importance to direct a special attention to those portions of the tissue which pass across from one joint-surface to the other. Atrophy of the pannous tissue can still further be promoted in another way; namely, by active and passive movements of the joint. In the fetal state a physiological pannus is developed at those points where, during the condition of rest, the joint-surfaces do not come in contact. The same cause partly determines the existence of a pathological pannus, which also is chiefly developed on those parts of the synovial surface which, on account of a forced condition of rest, do not come in contact. By motion, on the other hand, these pannous surfaces will come together, and their newly formed vessels will be forced to atrophy. Furthermore, every synovial membrane which has been the seat of a hyperplastic inflammation has a tendency, during its process of recovery, towards contraction (*indskræmping*). The stiffness of the joint, which is a result of this, may be best counteracted by a timely use of movements. These also promote the circulation of the blood and lymph, and are active agents against that form of muscular atrophy which, as a rule, is present in joint-affectations of long standing.

Dr. Mezger recommends to his patients, both in acute and chronic cases, a moderate use of the affected joint, to an extent which is limited by the production of pain. Passive movements are also used by him at the same time. He has treated several hundred cases, during the past fourteen years, by his peculiar system, and in no

instance has he seen bad results follow upon the moderate use of movements. He is of opinion that many cases pass into the suppurative stage on account of the absolute rest which is enforced by the forms of treatment which are in common use; and those instances of suppuration which have developed while under his own treatment, he thinks would have suffered in the same way, even though manipulation and movements had not been employed.

According to the views of Candidate Kier, Dr. Mezger's chief merit consists in the fact that he has separated massage from the system of therapeutic gymnastics, of which it forms a part, and that he has studied its effects upon disease more thoroughly and completely than has ever been, or could have been, done while it remained in the position of an accessory to other treatment. Mezger has elevated massage to the dignity of chief therapeutic means in his treatment of joint-affectations, and passive movements assume with him a secondary importance. Mr. Kier thinks that no one who has practically observed the effects of his treatment will be disposed to deny that his system of manipulations constitutes one of the most powerful remedies for combating synovitis—acute, chronic, serous, and hyperplastic.

At a meeting of the Medical Society of Copenhagen on the 25th of September, 1872, Dr. P. Wingé made some practical remarks upon Mezger's method of treating various forms of disease by massage, which he had personally examined during a visit of three weeks' duration at Bonn. (*Norsk Mag. for Læg.*, 3d Ser., 2d Vol., No. 11.) He describes it briefly as consisting essentially in kneading, rolling, percussing, and rubbing the parts which are the subjects for treatment. Whenever these are hairy, Dr. Mezger has then shaved before commencing his treatment, for when this is omitted the manipulations are apt to excite an inflammation about the roots of the hairs, and must be suspended until it subsides. The operator sits in front of his patient on a low stool, and begins by oiling the part with perfumed lard. He rubs strongly whenever indurations, infiltrations, or effusions are to be dealt with, and follows from below upwards the course of the lymphatic vessels in the extremities. When the knee-joint is the subject of treatment, he works across the joint with the fingers of one hand, on both sides, below the patella, pressing inwards with more or less force; while the fingers of the other hand work in the same manner, upwards along both sides of the patella, over the capsular ligament, or any ligament which is felt to be swollen. This process is continued from three to five minutes. He then grasps the joint with his right hand, and, pressing firmly, rubs upwards over the patella, as high as the superior insertion of the investing ligaments. This is repeated a number of times, varying according to the circumstances of the case. The applications are repeated once or twice every day. As the method of procedure is the same in principle for the other joints (the hip-joint, as we have already seen, being seldom treated by massage), this single example will suffice.

Passing over Dr. Wingé's explanation of the theory of the mode of action of massage in synovitis, which is essentially the same as that which has been much better expressed by Candidate Kier, I will give a few of the cases which he reports as having been treated by Dr. Mezger under his own observation. It is to be regretted that his visit continued only three weeks, for he was unable to follow up the ultimate results in any case.

CASE I.—A merchant, aged sixty-two, twenty years ago had a synovitis of the left knee, which subsided

under rest and other treatment, and left him well. Ten years ago he injured the same joint by being thrown from a wagon. A large effusion resulted, which was absorbed after a time, but was followed by several relapses, and the patient walked with difficulty and uncertainty, being very liable to falls. Mezger diagnosed a chronic synovitis levis, pannosa, and treated him three times a day by massage. Dr. Winge saw fifty applications made, and reports that the improvement, up to the time of his departure from Bonn, was very decided.

CASE II.—A gentleman, aged forty-five, had had disease of the left hip-joint when he was five years of age. Twenty years ago was attacked with an inflammation of the left knee, and received treatment for a year, recovering with a stiff joint, and a subluxation backwards of the leg on the thigh. Five and a half years ago he had another attack of inflammation in the knee, attended with pain and loss of power of locomotion. He came to Mezger on crutches. A diagnosis was made of synovitis chronica, hyperplastica, levis, cum ankylose. After eight days of treatment by massage, the patient could walk with the aid of a cane. The ankylosis and the posterior subluxation were of course unaltered, but the inflammation was removed.

In treating synovitis of the ankle-joint, which is complicated with flat-foot (talipes valgus), Dr. Mezger either treats both conditions at once, or waits until he has improved the position of the foot before he proceeds to treat the joint-inflammation. To accomplish the latter he arranges the shoe so that the inside of the foot is well supported, and brings the heel forward under the plantar arch.

In chronic rheumatic inflammations of the joints, accompanied by stiffness and contractures, Mezger gives a tolerably good prognosis when the soft parts alone are involved; but when the bony and cartilaginous tissues are invaded, his prognosis is decidedly unfavorable. He never uses chloroform in treating such cases, because he does not employ very forcible manipulations and movements. He often ruptures pseudo-membranous formations; but he carefully avoids exciting an inflammatory reaction, which might result in the production of stronger adhesions than before existed, and thus render his treatment more harmful than beneficial. Rheumatic distortions of the fingers, when treated by his method, are sometimes very painful: the wrist-joint is less so. The ankle-joint is apt to be more painful under treatment than the knee, but much less than the fingers and wrist.

CASE III.—A gentleman, aged fifty-eight, had suffered from rheumatism for a long time, and for the past year had had a persistent swelling and infiltration in the fingers and wrists; the thumbs not being involved. When he came to Dr. Mezger he was so helpless that he could neither open a door nor dress himself. He was treated at first by massage, and then by flexion and extension of the stiffened joints, for the purpose of rupturing the pseudo-membranes. In the three weeks that he remained under Dr. Winge's observation he improved so much that he could flex his wrists very well, and could write his name; but the fingers still remained quite stiff.

CASE IV.—An officer, aged thirty, with an inherited tendency to gout and rheumatism, was attacked with a rheumatic inflammation in both ankle-joints during the Austrian war in 1866. He recovered under the treatment which he received at that time. In 1870 he took part in the French war, and again was attacked with rheumatism of the ankle-joints. When he came to Dr. Mezger he could scarcely walk, and there was a good deal of infiltration present, especially about the

malleoli. His ankles were at first submitted to massage, and then flexed, extended and rotated, to rupture the pseudo-membranes. His improvement was very rapid: after two weeks of treatment he went home well.

CASE V. is that of a young Hollander who sprained his ankle severely a few days before coming to Dr. Mezger. He complained of great pain on pressure, or on attempting to use the joint, and there were large ecchymoses beneath the skin about the ankle. Massage was commenced at once, notwithstanding the pain which it excited in the beginning, and after six applications (three days) the patient was entirely well, and able to jump down from a sofa to the floor without causing himself the slightest pain.

After describing these and similar examples of the good effects of Dr. Mezger's method in joint-affections, Dr. Winge went on to give an account of his treatment, by the same means, of various other conditions, such as muscular atrophy, neuralgia, mastitis, chronic ulcers, etc. These do not now concern us, and we will follow him no further, but turn to a paper by Professor Nicolaysen in opposition to Mezger's system of treating joint-diseases (*Norsk Mag. for Læg.*, 3d Ser., 3d Vol., No. 1). The professor denies that Mezger has the right to claim the credit of having developed a new method of treatment, since massage, as he understands it, is merely a form of manipulation which has been and is used in many other parts of the world; and he gives a historical survey in support of his statement. He admits that massage is of great value in the treatment of sprains; but in inflammations of the joints he would restrict its employment entirely to the after-effects of disease; laying down the rule that all inflammation must have subsided before manipulations or movements can be at all permissible. This extreme conservatism, on the other hand, has been attacked by the Danish supporters of Mezger's system, on the grounds that it is partly based upon theoretical objections, and partly on Nicolaysen's omission to carry out, in the treatment of joint-diseases by massage, the rules of procedure which Dr. Mezger has laid down as essential to success.

THE WATER OF THE RED SULPHUR SPRINGS IN THE TREATMENT OF DISEASES OF THE HEART AND LUNGS.

By R. C. VAN WYCK, M.D.,

CULPEPPER CO., VA.

I wish to call the attention of the profession to a mineral water which has been known and distinguished for the past sixty years, though doubtless known to the medical profession at the North,—yet the virtues of which have been but little credited, or, if so, have erroneously been considered or forgotten.

These waters have been long resorted to by invalids suffering from pulmonary and throat diseases principally, though they are equally efficacious in other subacute affections.

The water of the Red Sulphur Springs takes its name from a peculiar deposit of a beautiful lake-color adhering to the sides of the marble slabs, wood, etc.; and is found to be a precipitate of sulphur, ferrous salts, and the vegetable matter of the "red lichen" deposited by alluvial process in the neighboring soil. This water, says Prof. Augustus A. Hays, M.D., of Roxbury, Mass., who has subjected it to a rigid chemical analysis, is perfectly colorless and transparent;

when agitated, has an agreeable sparkling appearance. Its odor is that of hydro-sulphuric acid mixed with earth or clay, the latter being retained after the hydro-sulphuric acid is dissipated or destroyed. In taste it is hepatic, cooling, and invigorating. By ebullition it does not immediately become turbid, gases escape, and when reduced in volume by evaporation, deposition takes place. The specific gravity of this water, compared with pure water at the same temperature and pressure, equals 1.00029. Its temperature is 54° F.

Chemical Analysis.—Fifty thousand grains (about seven pints) of the water, from which the hydro-sulphuric acid had been removed, afforded by the usual processes 2698 grains measure of gases, or one volume of gases from 18½ volumes of the water.

Ten parts of the mixed gases are made up of—

Carbonic acid gas.....	4.19
Nitrogen gas.....	4.77
Oxygen gas.....	1.04

10.00

A well-sealed bottle containing the hydro-sulphuric acid gas in the water, afforded for 50 parts of water 3.088 of mixed gases, or one volume of gases from less than 17 volumes of water.

Consisting of—

Carbonic acid gas.....	1.245
Nitrogen gas.....	1.497
Oxygen gas.....	.260
Hydro-sulphuric acid gas.....	.086

3.088

Gaseous contents of a gallon, or 231 cubic inches:

Carbonic acid.....	5.750
Nitrogen.....	6.916
Oxygen.....	1.201
Hydro-sulphuric acid.....	0.397

14.266

Fifty thousand grains (about seven pints) of the water afforded by evaporation in the air at 240° F. a light yellowish-brown matter, which, after it had been carefully dried, weighed 20.56 grains. At the temperature of 240° F. this residue becomes changed, and suffers a loss of weight, being reduced to 17.55 grains. This residue contains the saline particles of the water, and is composed of—

Silicious earthy matter, containing traces of oxide of iron and ammonia, probably suspended merely.....	0.70
Sulphate of soda in a dry state (which forms with the water 802 grains).....	3.55
Sulphate of lime.....	0.47
Carbonate of lime (lime dissolved in carbonic acid).....	4.50
Carbonate of magnesia, forming fluid magnesia.....	4.13
A peculiar substance containing sulphur combined with organic matter (the "sulphur compound").....	0.27
	20.55

The "sulphur compound," says Dr. Hays, which forms a part of the saline contents of this water, has never been described, if it has ever been met with. While in its natural state, and out of contact with atmospheric air, it is dissolved in the water, and forms a permanent solution. Air, acids, and other agents separate it from the water in the form of a jelly, and alkaline carbonates, alkalies, water, and other agents

re-dissolve it. It has no acid action on test fluids, but bears that character with bases, and forms compounds analogous to salts. In its decomposition, ammonia is formed, and hydro-sulphuric acid is liberated; or if heat be employed in the experiment, sulphur is separated. It combines with the oxide of silver, and forms a salt of a reddish-purple color, in the form of flocculent precipitate, which dissolves in pure water; with the oxide of lead, a yellowish-white powder; and with the oxide of copper, a pale-blue salt in fine powder. In these compounds it remains unaltered, and may be separated from them and transferred to other bases.

Mixed with a small quantity of water, and exposed to the temperature of 80° F., it decomposes, and emits a most offensive odor of putrefying matter with hydro-sulphuric acid gas. It is to this property that the hydro-sulphuric acid gas in the water is due, and to the oxidation of a part of this compound most of the sulphuric acid found in the compound may be referred.

There are traces of chlorine in some specimens, but at most only 0.13 grs. of chloride of silver could be separated from 10,000 grs. of water; this substance being rarely absent from natural waters that have penetrated the earth. This substance (sulphur compound) was thought to be analogous with *barégine* and *glairine* of the *Eaux-Bonnes* and *Cauterets* in the Pyrenees, but Dr. Hays thinks it is a substance new and peculiar, and seems to be an azotized base, and so combined as to neutralize the distinctive characters of sulphur. The hydro-sulphuric acid gas found in the water is produced through the agency of this body; either by its action on the sulphates present, or more probably the substance disengages hydro-sulphuric acid before reaching the surface of the earth, abstracting oxygen from air already dissolved in the water. It is in favor of this view that less oxygen is in this than in common water. I believe no trace of uncombined sulphur can be found in it in its fresh state; and when I fermented it, "*hydro-sulphuric acid*" was the form it appeared in. All the sulphur in this compound is therefore fitted to be absorbed in the animal system—an important medical fact; and it is therefore more than probable that the sulphur compound in this water is the principal medicinal agent contained in it, although its action in combination with other constituents may be necessary to produce the effects for which this water is so justly celebrated.*

Its action.—The action of this water when taken into the system is cathartic, narcotic, diuretic, diaphoretic, sedative, alterative, and tonic.

The most marked effect of this water is a reduction of the pulse. It has been known to diminish it from 10 to 20 pulsations in 24 hours. In my own case, on the evening of my arrival, it was 89; the next morning it was 69. Its action in this respect resembles digitalis. It increases the volume, and diminishes the pulsations. Its sedative action is most marked in moderately small doses, say four to six glasses per diem. In larger doses it acts like the infusion of digitalis as a diuretic. In small doses of two to three glasses per diem it acts as a cathartic, producing very often full and even copious evacuations. This is most always observable at first on commencing the use of the water, but the cathartic effect soon subsides; and if not, can be easily controlled by exercise, warm baths, or small doses of opium. In larger doses, from twelve to thirteen glasses per diem, it produces free diuresis and constipation. The latter symptom may easily be obviated by using a teaspoonful of table-salt in a glass of water before breakfast. It acts

* See Dr. Burck's book, *On the Action of the Mineral Waters of Virginia*.

freely as a diaphoretic if exercise be freely taken directly after drinking, which modifies very materially the excessive cathartic or diuretic action. Its action as a soporific is decidedly marked; patients that have been unable to sleep for months soon enjoy a calm, refreshing sleep. Its tonic action I believe is by improving the appetite, which is always improved after drinking the waters for a short time, and I may remark is characteristic of all sulphur waters. As an alterative its effects are shown very markedly, especially in phthisical persons, by a more free respiration. Very often the first thing that convinces the consumptive that he is improving, is that he "breathes easier." The expectoration is increased at first, but the patient expectorates more easily, and soon the expectoration becomes thicker, less in quantity, and finally disappears. I can recall one case where the cough entirely disappeared in four weeks from the use of the water. One patient in particular, who was troubled with night sweats for the past six months, was entirely cured in ten days by the faithful use of the water.

The introduction of this water into the system exerts a great influence on the circulation, and consequently on the mucous surfaces that are in a morbid condition; and when we consider that the greater portion of the fluids taken into the stomach are directly conveyed into the circulation by the absorbents, we can at once perceive that the great hygienic power of this water is dependent on the characteristics enumerated, all of which, combined, act as a singular alterative in equalizing an excited circulation, in correcting the highly acrid and vitiated secretions of an irritated mucous membrane, by modifying the fluid that supplies the matter for that secretion; and that by sending to the heart and lungs also a modified supply of blood, it calms these organs by producing in the latter a condition favorable to the proper performance of the functions of oxygenation, and by soothing the irritation of the former, causing it to send forth its stream with a milder impetus; and moreover, by diffusing more equally the capillary circulation, and in return obtaining not only a more moderate, but a more healthy supply.

Having thus briefly considered the action of the water, I will now enumerate the diseases in which I have seen the waters beneficial, and the vast experience of others who have long watched its action. These diseases are: chronic phthisis, chronic laryngitis, chronic bronchitis, subacute pleurisy, pericarditis with effusion, hydrothorax, functional disease of the heart, nervous irritability, hypertrophy of the heart, Bright's disease, cirrhosis associated with ascites.*

This water is contra-indicated in all acute diseases, in plethora or apoplectic tendencies, in chronic diarrhoea and dysentery,† in acute and far advanced phthisis, especially phthisis associated with diarrhoea, and in any acute disease of the heart or lungs. There are two stages of phthisis in which the Red Sulphur water gives prompt and decided relief. One is where the deposit is small and the development slow, associated with occasional hemorrhages. In such cases the water seems to arrest the deposition, to control the

night sweats, at the same time to increase the flesh, and impart tone and energy to the system. The second form is when softening has taken place to a limited extent, and inflammation of the contiguous tissues has resulted in purulent expectoration (i.e. "chronic caseous pneumonia, with interstitial deposit"). The question here to be decided by the family physician is, whether the condition of his patient is such as to admit of a fair probability that he will be able to return to his home in the event of a failure. If diarrhoea alternates with the expectoration and cough in passing through the limestone regions, the bowels frequently give way, and death ensues on the journey. The physician should carefully consider all things, and no patient should attempt such a trip unless he is physically able to endure such accidents, should they occur.

Having enumerated those diseases which experience has proven are best benefited by the waters, I will close this article with a brief consideration of the place, its location, etc.

The Red Sulphur Springs are situated in Monroe Co., West Virginia. They are best reached by taking the Chesapeake and Ohio Railroad to Talcott station, thence by stage thirteen miles to the Springs, or the Virginia & Tennessee Railroad to Dublin station, thence by stage forty miles. They are situated in a valley, surrounded on two sides by lofty mountains. The springs are situated at the south-west portion of the valley, and the water is collected into two marble basins, sheltered by a noble pavilion in the form of a Grecian temple; this structure alone was erected at a cost of \$6,000. The buildings are situated at the bases of these mountains,—a most wonderful mistake, as there is ground within three hundred yards adjacent, which is a most delightful site for hotel buildings.

These buildings were erected in 1840, and since the war the place as well as the buildings has been suffered to run down; still, the buildings are comfortable (though somewhat damp), and in a dry season are comfortable enough for all patients. The great drawback to the Springs is the location of the buildings, built at the bases of the mountains, which is quite damp. They are subject to dense fogs every morning, and the sun disappears behind the mountains about 4 o'clock in the afternoon. But in spite of the serious drawbacks, invalids, and consumptives at that, do improve often in the dampest seasons. What is needed is an enterprising stock company to buy the Springs. The lands, including the springs and grounds, are estimated at 1,400 acres, and can be purchased for \$25,000. If the buildings were in a suitable place, so that invalids could have the sun continually, where dryness and pure air could be freely enjoyed, which may easily be done, I am satisfied that the Red Sulphur Springs would rank first among curative waters, and would justly bear the name "EXCELSIOR." For when a mineral water is found that will cure or even alleviate pulmonary phthisis, we may all rest assured that it will be a great resort for thousands from far and near. It is not, however, necessary to go to the Springs to get the virtues of the water, as it can be bottled. The writer of this bears testimony to having used it for the past month at home. The water keeps better in cool weather, as heat seems to cause a precipitate. It is very volatile, and does not keep well after being uncorked. When well kept it seems to act just as well as at the Springs.

I have been careful not to overestimate anything in regard to this water. I do not consider it by any means a panacea for consumption, and cases that are

* In these two latter diseases the waters deserve a trial; no cases, to my knowledge, have tried the waters.

† I have thought best to exclude diarrhoea and dysentery from the list, as the Rockbridge alum-water is much more efficacious. Dr. R. Bradford, who practised medicine at the Red Sulphur, says: "The effect of this water in reducing the pulse is one of the numerous, singular, and powerful properties belonging to it. It lessens arterial action to such a degree, that it seldom fails to remove fever, difficulty in breathing, and pain in the chest. When the patient is restricted to the proper regimen, this water may be taken with greater advantage in pulmonary cases than any other remedy I have seen employed for that purpose. It is also an important remedy in enlarged spleen and liver, and in diseases of the mucous membranes generally."

selected for its use require judgment. It does now and then fail in best-selected cases, but it is easy to know this; when the water increases the pulse, produces fever and constriction of the chest, it is not adapted,—those cases seem to be in the proportion of one in fifty.

The water seems to act more efficaciously when active exercise is combined. It is incompatible with stimulants as a rule,—though some patients are benefited by the combination. Vegetables are, as a rule, incompatible. The most agreeable and nutritious way of drinking the water is with cream and milk, and I do not find it incompatible with cod-liver oil, which is my daily medicine—Red-Sulphur water, cream, milk, and cod-liver oil. In conclusion, I will truthfully state, that having been an invalid for the past four years, having sought many climes, including boasting Colorado, I have never, since my illness, enjoyed better health since the five weeks spent at the Red Sulphur Springs, and four months on a farm in the glorious Piedmont valley of Virginia.

AN ABORTIVE METHOD OF TREATMENT IN CERTAIN CASES OF CORYZA AND ACUTE INFLAMMATION OF THE FRONTAL SINUSES.

By J. S. PROUT, M.D.,

OF BROOKLYN, N. Y.

I WILL say nothing of the symptoms of coryza, as probably all of my readers have had one or more attacks; but will remark that, in my own experience, the characteristic symptoms of frontal catarrh, as I call the inflammation of the frontal sinuses, are a dull, heavy frontal ache, not to be accounted for by the coexistence of gastric disturbance or *biliousness*, and a very painful feeling of distention in the frontal region in stooping forward.

The treatment is unsatisfactory to a high degree. Niemeyer, in his Text-Book of Practical Medicine (Translation, Vol. I., p. 291), says: "Various abortive methods of treatment for acute nasal catarrh have been proposed; but none of them" (he mentions six) "have obtained general approval." Among other things he recommends the Russian bath.

Cohen, in his excellent work on the Diseases of the Throat, mentions various remedies that may be tried. He speaks of three, any one of which will generally cause a coryza to abort: 1st, a grain or so of opium; 2d, a dose of alcohol at bed-time; or 3d, the inhalation of chloroform.

We may try these means on ourselves, if we choose—but for obvious reasons we cannot trust our patients with them.

We need a remedy that is safe, easy to use, that we can put in the hands of our patients without fear of unfortunate results, and that does not waste our time; a remedy that physicians in their own persons, as well as the laity, will not consider worse than the disease itself.

Let me, then, without further introduction, state that I have, in my own person, and with patients, often been able to arrest the disease in the course of an hour or less, by taking or giving large doses of the official tincture of the chloride of iron, 20 or 30 minims, as soon as possible after the cold is "caught." I generally find that in about half an hour there is a decided amelioration of the symptoms, which may be permanent, in which case I take or give no more of the

tincture, or the improvement may pass off in two or three hours; in which case, the dose must be repeated. This may be required three or four times.

I have had numerous attacks of frontal catarrh, which I have thus caused to abort. I have had the same good fortune with coryza accompanied by sore-throat.

In other cases, perhaps on account of greater severity or from delay in commencing the treatment, I have not obtained permanent benefit from the use of the tincture. In my hands, therefore, it is not a specific.

On the 21st October of this year, I called the attention of the members of our County Medical Society to this method of treating coryza. I have recently received a note from a member of the Society, Dr. Edson, who was present at the meeting referred to, giving his experience in regard to it, which is so entirely satisfactory and in accord with my own, that I prefer to copy it, as the record of an unprejudiced observer, rather than detail any of my own observations, which might appear unduly partial.

He writes (Nov. 28th):—

"Mr. B., a lawyer, has for years been particularly subject to colds, with frontal headache, difficulty in respiration, and the other usual attending symptoms. He usually spoke of himself as being a sufferer from catarrh. During the months of August and September his affection generally assumed a severer form, not very unlike hay-asthma.

"Upon returning home on the evening on which you spoke before the Medical Society of the successful use of the muriated tincture of iron in similar cases, I found Mr. B. in the early stage of one of his attacks. 'sneezing and wheezing,' with creeping chills, eyes suffused, etc., etc., presenting that peculiarly disconsolate appearance so general in this complaint. I suggested to him to try the tincture in half-drachm doses, repeated if necessary. In less than half an hour after taking the first dose he expressed himself as feeling decided relief. Another dose in due time, and his attack was cut short, decidedly aborted. Since that time, whenever he feels the hand of his old enemy upon him, he takes a timely dose of the tincture, and thus far with the happiest results.

"This is one of several cases in which I have prescribed this remedy for similar affections, and with such marked advantage that I have great confidence in its efficiency in this class of cases.

"Yours very truly,

"B. EDSON, M.D.,

"140 Park Place."

What need I say more to obtain for it a trial?

A convenient form for extemporaneous prescription is—

R. Tinct. ferri chloridi,
Glycerinae, ℥i. ʒiv.
M.

S. One teaspoonful in a wine-glassful of cold water, through a glass tube, to be repeated according to circumstances. The glycerine in part conceals the iron taste.

There is a slight diuretic action. I have found no unpleasant effect on the bowels, and only a slight feeling of discomfort, which soon passed off, when it was taken on an entirely empty stomach.

How are we to explain this action of the iron tincture? Dr. T. Clifford Allbutt, an excellent observer, says: "In iron we have two kinds of value; its value in ordinary small doses and in mild forms" (he is speaking of neuralgia), "when it removes simple anemia; and its value in large doses—doses such as half

a drachm to a drachm of carbonate of iron, or of twenty to thirty drops of the sesquichloride tincture—when it seems, apart from the presence of any definite anemia, to have a *special effect in modifying the morbid state of nerve-tissue.*"—(Liverpool and Manchester Med. and Surg. Reports, 1873. Quoted in Braithwaite's Retrospect, July, 1873, p. 41.)

Let the last eleven words (italics my own) of this quotation, then, for the time being, explain how it is that 20 or 30 minim doses of tincture of the chloride of iron abort coryzas.

December 3d, 1873.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

GOUT.

The case was interesting in the fact that it illustrated a wonderful development of the disease in a boy aged twenty, without any real cause, unless it was an hereditary tendency. His fingers had the appearance of a bunch of carrots; nearly all the joints of the body contained gouty deposit, and the helix of his ears was filled with *tophi*.

CHRONIC DYSENTERY.

The old lady, aged seventy, had been sick five weeks, and came into the hospital with a history of diarrhoea. The case was interesting as illustrating one fact, namely, that it is important to go back to the history of a case and determine whether the first attack was one of diarrhoea or dysentery, which may give rise to an intelligent conclusion as to whether the present condition of a patient is one of chronic diarrhoea or chronic dysentery. The patient says she was taken with diarrhoea; had quite a number of passages every day, but that they were attended with considerable pain, and accompanied with a moderate discharge of blood and mucus. That was the key to the case. It was a case of chronic dysentery, engrafted upon an acute attack. An important element in the treatment of cases of chronic dysentery consists in a careful regulation of the diet for the patient. The objects to be had in view in regulating the diet are nourishment and finding some article of food which can be retained and digested. To obtain these is not infrequently trying to the ingenuity of the physician. Among the remedial agents employed, the fluid per-nitrate of iron and a decoction of the root of the *Rubus Canadensis* are sometimes very serviceable. Abscess of the liver sometimes occurs in connection with chronic dysentery.

SUBACUTE GASTRITIS.

The subject, who presented the disgorgement consequent upon an attack of this disease, was a woman aged twenty-eight, and married. She had been drinking *gin* for about ten days, had *accidentally* stepped from a ferry-boat into the river, and finally brought up at the hospital suffering from an almost incessant nausea and vomiting; *gin*, subacute gastritis, and vomiting succeeding each other.

Carbonic-acid water, pounded ice, and rest to the stomach were the chief features of the treatment. The general restlessness which was manifested in the case was well controlled by hypodermic injection of morphine. Rest to the stomach is obtained in severe and

protracted cases of vomiting by nourishing the patient with injections of milk, beef-tea, and eggs. When the bowels are not moving in consequence of diarrhoea, patients can be very satisfactorily sustained in this manner, and perfect rest secured for the stomach.

LOCOMOTOR ATAXIA.

A case was noticed which recalled the fact that sensation is always diminished below the point in the body where the band passes about it. This may materially assist in determining the exact point of lesion in the spinal cord. Trace the sensation downwards to the point upon the body where it begins to diminish, and follow that line around to the spine.

ADMINISTRATION OF ETHER.

The administration of potass. bromid. grs. xxx., previous, and the same amount immediately following, or as soon as the patient can conveniently swallow, after the administration of sulphuric ether for the purpose of producing anaesthesia, is now regularly resorted to. The effect is to prevent the vomiting which so commonly follows the use of the anæsthetic.

IRREGULAR ACTION OF THE HEART

is very nicely controlled in very many cases by the administration of ext. nux vomica gr. $\frac{1}{4}$ three times a day. These doses may be increased to gr. $\frac{1}{2}$ t. i. d. It is said to be much more efficient and reliable than digitalis.

NURSING.

The question is very frequently asked, prior to the first confinement, Whether it will be policy for the woman to attempt to nurse the child? There are certain inquiries which may throw some light upon the "new probabilities" in the case.

First, Have the menstrual functions been properly performed prior to pregnancy? There is no special connection between the function of lactation and the function of menstruation, except that the cessation of one may indicate the commencement of the other; but it not infrequently happens that uterine disease, existing prior to pregnancy, perhaps returns after confinement, and then may materially interfere with the proper performance of the function of lactation.

Second, Examination of the breast during the period of pregnancy. As early as the fourth month a fluid can be pressed from the nipple, and at a later period the quantity of milk which can be pressed out is sometimes considerable. If the milk which can be obtained in this way contains an abundance of colostrum, the probabilities are that the woman will furnish sufficient milk after confinement to warrant the commencement of rearing the child by nursing the mother's breast. This rule is not invariable, but is sufficiently good to furnish probable results.

The woman commences nursing her child, and for two, or three, or four months the supply of milk is sufficient; but at the end of that time the supply is not equal to the demand, and artificial measures must be employed. What shall the new nourishment consist of? Substituting the milk of the ass or goat is believed to be a mere fancy, if circumstances are such that fresh milk from the cow can be obtained twice daily.

The most important difference between human milk and cow's milk exists in the casein. The casein of cow's milk forms itself into a hard, large lump, and very frequently coagulates in such manner that the child will vomit long pieces of coagulated milk, varying in size according to the size of the canal through

which these pieces must pass. To correct this result, the addition of lime or soda water to the cow's milk should be habitually resorted to in those cases where the cow's milk is not readily assimilated.

One drachm of carbonate of soda may be added to six ounces of water, and a tablespoonful of this added to every feeding of the child.

A tablespoonful of aque calcis may be employed in the same manner all through the period of nursing from the bottle, without incurring any bad results, but, on the contrary, secure good results.

The dilution of cow's milk will be necessary, and the amount of dilution will vary according to the age of the child and the quality of milk. Good cow-milk should be used for young children, one part water and two of milk, and the lime or soda water added to this.

During the summer months, when the child is most liable to be attacked with diarrhoea, if the child shows any tendency in that direction, the milk should be sweetened with sugar of milk and not cane-sugar.

ROOSEVELT HOSPITAL.

FRACTURE OF FEMUR.

It is believed by Dr. Lagarde, house-surgeon, that the best results are obtained in this class of cases, with reference to shortening, when the limb has been kept in an extended position by means of Buck's extension apparatus for several days—at least until all inflammatory action has subsided—before the permanent retentive apparatus is applied. It has been found that when a fractured femur has been placed in a permanent splint within a few hours after the injury has occurred, a much larger amount of callous induration occurs about the seat of fracture than when delay is made in the adjustment of a permanent apparatus until all inflammatory action has subsided. When the inflammatory action has subsided, no ether is used while applying the permanent splint. In the examination of some reports setting forth the extremely satisfactory results obtained by the employment of certain carefully devised apparatus in connection with the application of the permanent splint, with reference to the item of shortening, the question at once suggests itself, whether the results obtained may not be as much due to the fact that the adjustment of the permanent splint was delayed until all inflammatory action had subsided, as to any real superiority of the apparatus itself. It is doubtless a good principle to be governed by, in the treatment of fractures in general, to wait until inflammatory action has subsided before permanent fixtures are applied to the limb. One practical objection to the adoption of this plan is, the minds of the laity are "set," and they are very apt to insist that the bone shall also be "set at once" after a fracture has occurred.

SYNOVITIS, CHRONIC.

This class of cases are now being treated by employing passive motion, as much as is possible for the patient to bear without producing pain. If pain is developed, place the patient in bed, secure perfect rest, and as soon as the inflammation has subsided, again resort to passive motion. It is feared that some kind-hearted doctor will get into difficulty in attempting to apply this principle in private practice.

EXCISION AT ELBOW-JOINT.

Two cases in whom this operation had been performed, were additional instances of the triumphs of

modern surgery. In one case the motions retained by the limb were remarkably perfect. Pronation and supination, flexion and extension, could be well performed. The operation had relieved the man of the presence of an almost useless member, and given in place of it a limb which will become as useful as was the arm previous to any attack of disease.

HYDROCELE.

A somewhat remarkable result was obtained in the treatment of a case of hydrocele by using an injection of pure Lugol's solution. The entire tunica vaginalis was removed, and the patient was making a rapid and satisfactory recovery.

OXYGEN IN PHTHISIS.

The employment of oxygen-gas in the treatment of phthisis was continued for some time, but has been discontinued on account of the expense attending its use.

Dr. Hutton, house-physician, informed me that during the time it was employed, the patients to whom it was administered did exceedingly well. The improvement in the general condition of the patient was such as to warrant its adoption in cases where expense was a secondary consideration. Its effect was certainly palliating, and perhaps retarding to the progress of the disease.

Progress of Medical Science.

GLYCERINE AS A MEANS OF DISGUISED MEDICINES.

—We desire to call the attention of our readers to the use of glycerine as a means of disguising medicines, especially those of an oily nature. Some time since it was announced that if castor-oil be mixed with an equal part of glycerine and one or two drops of oil of cinnamon to the dose, it can scarcely be recognized. We have used this mixture a good number of times, and can confirm all that has been said of it. Children take it out of the spoon without difficulty. We have given it to doctors without their discovering that they were taking castor-oil.

In typhoid fever and other diseases in which turpentine is indicated, patients often object very much to its taste. The addition of half an ounce of glycerine to a six-ounce emulsion disguises almost completely the turpentine, especially if a drop of oil of gaultheria or of other volatile oil be added for each dose.

No doubt the principle is capable of wide extension. It is said that cod-liver oil may be disguised with glycerine and whiskey; and Dr. Herbert L. Snow writes to the *British Medical Journal* that an addition of a small quantity of glycerine (about half an ounce to an eight-ounce mixture) will altogether obviate the sensation of astringency produced by the chloride of iron dissolved in syrup.—*Canada Med. Record.*

ACTION OF CARBOLIC ACID ON THE URINE.—When carbolic acid has been applied to a raw surface a peculiar change has been observed by Mr. W. A. Patchette to take place in the color of the urine. A blackish or dark olive-green discoloration occurs in from four to forty-eight hours, and the urine resembles an infusion of tea or digitalis to which a little iron has been added. The discoloration does not appear with any regularity or constancy, and may follow the internal use of carbolic acid, but unless poisonous doses have been given, the color is not so deep as that produced by the external application of the acid.—*London Lancet.*

VALERIAN IN DIABETES.—Dr. Bouchard, of *La Charité* Hospital, has been making a trial of valerian in diabetes. In diabetes without sugar the medicine did not seem to diminish the quantity of urine, but azoturia was obviously amended. The quantity of urea discharged in the twenty-four hours was much diminished; it decreased from forty-five grammes (about eleven drachms) to ten grammes (two drachms and a half). The same results were observed in diabetes mellitus. In these cases, when there existed azoturia together with glycosuria, the quantity of urea always diminished under the influence of valerian. In some cases there was less excretion of water and sugar; but these effects seemed uncertain. Decrease in the production of urea was invariable. Valerian, therefore, prevents denutrition, and may be considered a saving remedy (*médicament d'épargne*).

Dr. Bouchard, in respect to this latter quality, quotes the customs of various Indian tribes, among whom the warriors during a month previous to going out to fight make use of valerian in every shape—in baths, in frictions, and internally. They ascribe to the substance the strength and courage which they feel in going through long marches, fatigue, and privation of food. This property of valerian has been observed in arsenic and bromide of potassium. Dr. Bouchard commenced with weak doses, which he gradually increased to one ounce of the extract, without having noticed any inconvenience.

APPLICATION OF GARGLES TO THE INTERIOR OF THE LARYNX.—*The Lancet* of November 1 says that at a recent meeting of the Clinical Society, Dr. H. Guinier, of Montpellier, was introduced to the Society, and showed, by means of the laryngoscope, that it was practicable to allow any fluid to pass beyond the epiglottis, and to remain between that organ and the vocal cords during the time occupied by a long expiration, or as long as the patient can "hold his breath." Dr. Guinier used water in his demonstration; the vocal cords were plainly seen through the fluid, and the operator also ejected the latter through his nose. Although the sensibility of the soft palate and parts adjacent is known to be, comparatively speaking, inconsiderable, a general impression appeared to exist among the members that much practice would be required on the part of the patient to bring about so successful a result as that achieved in this case by Dr. Guinier. The following rules must be observed and practised in the operation: 1. Raise the head slightly; 2. Open the mouth to a moderate extent; 3. Advance the chin and the lower jaw; 4. Sound, or make an intonation of sounding, the double vowel *æ*. The author remarks that, as a consequence of these four movements carried on simultaneously, the pharynx is widened, the soft palate and uvula are raised, the base of the tongue is depressed, and the liquid thus flows, by virtue of its own weight, into the laryngeal cavity.

ISCHEMIC HERNIA.—*The Dublin Jour. of Med. Sci.* of Sept. contains an account of a case of this exceedingly rare accident, which in this instance occurred to a woman aged about forty, and was brought about by lifting. The intestine escaped from the great sacro-sciatic foramen of the right side, and the tumor, which was about the size of a fetal head at term, extended across the left thigh below the gluteal fold, preventing the woman from sitting. Taxis reduced the size of the tumor somewhat, but its entire reduction was impossible.

CHERRY-LAUREL WATER AS A VEHICLE FOR HYPODERMIC INJECTIONS.—Professor Luton says that no

vehicle is better suited for narcotic substances, such as morphia and atropia, when administered subcutaneously, than the distilled cherry-laurel water. Besides adding its measure of hypnotic action to that of the principal medicament, it prevents, better than any other aromatic distilled water, the formation of mould, which readily takes place in solutions for hypodermic injections; being in this respect equal, at least, to eucalyptus water. Its contact with the tissues does not cause more pain than ordinary distilled water. When cherry-laurel water is injected alone, its physiological effects are the same as when it is administered by the stomach; but in an increased degree.—*Répertoire de Pharmacie*.

THE FATTY URINE OF HOT COUNTRIES.—Commenting upon Dr. Jules Creveaux's work on Chyluria or Fatty Hematuria of Hot Countries, the *Gazette Médicale de Paris* observed that this curious malady, hitherto unknown in our climate, has only been observed in Paris on subjects arrived from the isles of Bourbon, Maurice, etc., where it prevails in endemic form. In America, even, it is only observed between latitude 30° N. and 35° S. Another peculiarity of this singular affection, which is characterized by the emission of urine sometimes red as blood and sometimes as pale as chyle, is the diversity of opinion prevailing as regards its nature. Carter, of Bombay, and Beale, of London, believe that the chyle passes into the urine. Gubler considers it a lymphorrhagia of the uropoietic apparatus, and he explains the appearance of blood in the urine partly by the existence of blood-globules in the lymph, and partly by the coagulation of the solid matters of the lymph which have been deposited in the bladder in intervals of micturition, and which are only evacuated when the bladder is completely emptied by a forced contraction.

The author of the *brochure* cites a number of observations which go to support the opinion of M. Gubler.

According to Prof. Robin, the malady known by the name of chyluria is only a form of hematuria, a form in which the blood-plasma, passing into the urine, imparts to it its white color. Rayet and Cl. Bernard express the same opinion, and Bouchardat claims that the fat of the urine called chylus presents all the properties of the fat of the blood and not of the chyle.

According to Dr. John Harley the white matter of the urine is derived from the lymphatics and the blood-globules from a rupture of the capillaries at some part of the mucous membrane of the urinary apparatus. This vascular discharge is produced by helminth, the *distoma capensis*, which has been seen in all the cases from the Cape which he has examined.

According to M. Creveaux, naval physician, who publishes in his thesis the only case which he has observed, chylous or fatty hematuria is a product of two morbid conditions: one, general, marked by an augmentation of the fatty matter of the blood or lymph; the other local, marked by a lesion of vessels at some point of the urinary apparatus—lesion which produces the passage of uric acid, gravel, or the passage of helminths into the urinary apparatus.

During the past few years microscopic examination of the urine has shown the frequent presence of helminths, of their eggs and debris in the hematuria of hot climates.

Further researches, still, are necessary, however, to give us a full knowledge of this curious affection.—*The Doctor*.

A SUCCESSFUL REMEDY FOR TOOTHACHE.—This remedy consists in the use of injections which are ap-

plied to the gums in the vicinity of the diseased tooth. Dr. Dop has employed these injections in about one hundred cases. In twenty cases he used morphine, by which he obtained good but not permanent results; chloroform was found to be far preferable, and he now uses it exclusively. In sixty-two of eighty cases the results have proved extraordinarily favorable. Two drops suffice for an injection, which is made with the Pravaz, or ordinary hypodermic syringe. The cannula is gradually pressed into the gum, and is allowed to remain in position for a few seconds. When removed, pressure is to be made with the finger over the puncture. In the large majority of cases one injection suffices to stop the pain, but it is sometimes necessary to repeat it after twenty-four hours.—*Corr. f. Z. and Norsk Mag. f. Lægevidenskaben*, Nov. 11, 1873.

SPONTANEOUS EXPULSION OF A CALCULUS FROM THE BLADDER OF A FEMALE.—*El Anfitrion Anom.*, *Espanol*, July 31st, 1873, contains a letter from Dr. José Benjumea, of Casariche, detailing the following case: The woman was sixty years of age, had had urinary trouble for about ten years, and had, at different times, passed several small calculi, having some pain previous to their expulsion. She had also had a nephritic calculus within the last two years. The presence of a vesical calculus was suspected, but the patient was unwilling to have a sound passed, though she suffered extremely for the four months preceding its expulsion, which occurred in April, while making an effort to defecate. The stone was ovoid in shape, and weighed 65 grammes. It was 7 cm. in length and 4 cm. in diameter. In May, when Dr. B.'s letter was written, there was still some want of contractility at the neck of the bladder, in consequence of the great distention to which the parts had been subjected.

PROFESSOR MOSLER ON THE TREATMENT OF INTERNAL DISEASES BY THE INTRODUCTION OF LARGE QUANTITIES OF FLUID INTO THE INTESTINE.—Gustav Simon has recently demonstrated the possibility of making fluids penetrate the whole length of the large intestine, thereby causing no injury to the part, by means of forced injections per anum. His investigations were conducted on two patients, both suffering from fecal fistule in the right inguinal region. Water injected at the anus appeared at the fistulous opening in five minutes.

An important addition has been made to the investigations of Simon, in showing that the same result may be accomplished without the aid of forced injections. Instead of a syringe, a simple funnel or irrigator is used, to which an elastic tube is attached, provided with an olive-shaped tip. The olive-shaped tip being inserted at the anus, water is poured in at the funnel, and by raising or lowering the latter, the pressure of the column of water can be regulated as desired. To Alfred Heger belongs the credit of first suggesting this method, the advantages of which, he claims, are, that the apparatus is cheaper, easier cleansed, less liable to get out of order, and less readily permits admission of air. When the intra-abdominal pressure is under the atmospheric pressure, he thinks that but a very slight force will enable the fluid to enter the bowel. In giving ordinary clysters with this apparatus, it suffices that the body be in a horizontal position; but should it be desirable to fill the upper part of the large intestine, the intra-abdominal pressure must be decreased by a change of posture, and the patient is made to rest upon the knees and elbows, or better, with the upper portion of the body resting upon the breast and shoulders. By

this method five to nine pints of water could be easily introduced before the sphincter yielded or water escaped at the side of the tube. This constrained position, however, proving often very irksome, causing sometimes violent headache in patients who were feeble or suffering from cerebral congestions, determined Mosler to attempt to accomplish the same object while the patient maintained the recumbent posture. He found it necessary merely to lengthen the tube somewhat, and raise the funnel a little higher than Heger had done. In this manner he poured in over three quarts within fifteen minutes, without a drop escaping at the anus. In order to prevent too rapid dilatation of the intestine, the flow was frequently interrupted by compressing the tube. By thus introducing three or four quarts of warm water, he has been able to relieve the most obstinate obstipation which had proved rebellious to all other remedies.

In order to ascertain positively to what extent the fluid penetrated in the intestine, various experiments were tried. It was repeatedly found that wherebefore the injection the left inguinal region gave a tympanitic sound on percussion, after the injection it was dull. Experiments on the cadaver were made, but the loss of tonicity in the bowel rendered it incapable of retaining so large an amount of fluid. Finally, the question was settled by trial upon a patient who, in consequence of a gangrenous hernia, had a fistula at the junction of the colon ascendens with the cæcum. With the finger the pouch of the cæcum, as well as the ileo-cæcal valve, could be readily palpated. With the above-described apparatus one and a half litres of warm water were poured into the intestine, the funnel being held about two feet above the anus, the patient in the usual recumbent position. The fluid appeared at the fistulous opening in two minutes, before half the quantity used had left the funnel. The patient suffered no discomfort.

The conditions which furnish indications for the above method of treatment, Prof. Mosler groups under five heads, viz.: 1. The various forms of obstruction of the bowels, especially impaction of feces. 2. For the reduction of internal hernia, as hernia retro-peritonealis and diaphragmatica, or, perhaps, in case of any form of hernia. The great dilatation and loading of the intestine necessarily exert a powerful strain from within. This treatment can be admissible only in the early stage, before the intestine has become weakened and so easily lacerated. 3. In numerous diseases of the large intestine, especially dysentery. The twofold benefit is indicated from first washing away irritating detritus, and secondly, from the topical application of astringent and disinfectant fluids. 4. In the various forms of icterus, especially catarrhal, as well as in cholelithiasis. According to recent researches, injection of water into the intestinal canal increases the secretion of bile; the secretion, before thick and viscid, becomes more watery and freer, and thus tends to loosen any catarrhal plug accumulated in the duct, and perhaps drive before it impacted gall-stones. The 5th indication is found in certain conditions during the treatment of helminthiasis. In the treatment of tape-worm it not unfrequently occurs that the remedies given drive the worm into the colon, where it reattaches itself by suction and cannot be further expelled. One or two quarts of warm water, with equal parts of milk, thrown into the intestine, will often succeed in separating the head and cause its complete expulsion. For the oxyuris vermicularis, which inhabits not only the rectum but the whole large intestine, the advantage of this method is likewise apparent.—*Berl. klin. Wochens.*, 45.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, January 1, 1874.

ARMY STAFF RANK.

THE question of increased rank for medical officers in the army is one of as great importance as the profession can now be called upon to discuss. In our previous issue we referred in a cursory way to the means which are being taken to secure this end; the changes proposed; and the necessity for a concerted action on the part of the profession at large.

Whenever a proposition of such importance as the one before us is to be considered, it is always well to canvass the necessity for change. The latter is well set forth in the memorial of the American Medical Association upon the subject, to some points of which, for the benefit of our readers and others interested, we shall take occasion to refer.

The committee which prepared this memorial has certainly performed its task in a very creditable and satisfactory manner. The information has been gained as the result of much painstaking inquiry, and the opinions expressed are not only those of the army medical officers, but, we venture to say, of every physician in the country.

The first point noted is, that in every other corps of the army every officer except the surgeon has a prospect of attaining the rank of colonel in a given time. The average length of service required in other corps to attain such rank is twenty-five years, and that of lieutenant-colonel twenty years. In contrast with this is the fact that there are at least twelve medical officers who have each served upwards of thirty years, and who are still of the rank of major. This unjust discrimination is glaringly apparent to any one who will give the subject an impartial consideration.

If it can be proved that the medical officer does not require for the discharge of his duties as much culture and as much intellect as in any other branch of the service, then the discrimination is a merited one,

and as a profession we humbly abide the consequences. The opposite opinion, however, is now an admitted fact by every person, in or out of the army, who has had any opportunity for forming judgment in the premises. There is, in fact, no corps in the army that has not learned to appreciate and respect the medical corps, and this respect has been honestly earned and conscientiously maintained from the time that the American army as such first had an existence. There has hardly been a campaign in the general report of which some deservedly high compliment has not been paid to the medical staff, due acknowledgment of services rendered, and honest appreciation of the value of suggestions made in the care and transportation of the sick and wounded.

Not only do we maintain that the medical corps are on a par with any other in the army, but that as a corps it has a special claim for a recognition of services rendered. In the case of the vast majority of staff-officers the special education which fits them for their positions, which raises their qualifications to the required standard, is not only furnished by the government, but a good salary is paid them during their tuition. The medical man must obtain his education at his own expense, and this must be especially thorough to enable him to pass the ordeal of an army examination. We have not yet gone so far as to have an army medical school—which, however, we shall have eventually—and cannot expect that the Government can bestow upon army candidates the thorough medical education which the army boards require. We only mention the fact as one which should be taken into consideration in fixing a just premium upon the long and meritorious services of the medical officer. If there be any doubt as to what is required of the surgeon, and what he may perform, we have but to refer to the history of the army medical staff during the late rebellion. The history proved that the medical men who took part in this struggle were equal to every emergency upon the field or in the hospital; that in the organization and management of the latter they displayed a tact and ability which rose to the level of genius, and earned for themselves the reputation of the highest authorities in military hygiene and military surgery throughout the civilized world.

Chassaignac only a few years ago said to a distinguished American surgeon: "You have just reason to be proud of your country. America at this moment wields the surgical sceptre of the world." If justice be done to the army surgeon, if the records of the war prove anything, we must admit that the army surgeons have contributed to this enviable reputation as much, if not proportionately more, than any other class of scientific medical men. Coupled with these attainments, we have proved his fitness for his position as an officer. During the late war we often beheld the surgeon in charge of a hospital, with the rank of a first lieutenant, performing all the actual duties of a com-

mander of a post, and at the same time attending to the higher demands of his profession at the operating table, making resection, autoplasty, and amputation of the hip with a skill that would do credit to the occupants of our professorial chairs.

In the matter of strictly medical attainments, they were by no means behind their brethren in civil life. In every hospital the examination of cases was carried on with all the thoroughness possible with surrounding circumstances. Diseases were studied on a large scale, and to a purpose which makes the results of accumulated experience authoritative.

In the higher branches of medical as well as surgical research, the army surgeon has contributed his share. Not only has disease been studied in the generally accepted way, but all the refinements of microscopy have been brought to bear upon such investigations, and original observations of the greatest possible utility to science at large have been made by a more extended application of this instrument. In this connection we refer to that wonderful treasury of experience, the Medical and Surgical History of the Rebellion, which of itself is an everlasting monument of the industry and skill of the army surgeon, and which as a specially valuable contribution to our science, is unequalled anywhere. The Army Medical Museum, the work also of the medical corps, is of itself one of the most magnificent and valuable collections of specimens ever before brought together. This rebellion gave the best opportunity for the display of the scientific attainments of the medical corps, and has given to many of its members world-wide reputations as authors, observers, operators, and originators.

The Medical Library, already looked to as the national one, owes its all to the medical staff of the army, under whose auspices it was conceived, in whose care alone it has thriven beyond the calculation of the most sanguine medical bibliopoles. And yet the gentlemen who have arranged the medical and surgical history of the rebellion, who have brought the museum to its present perfection, the library to its present size, who have served the best years of their lives, who have used their brilliant attainments solely for the service of their country, who have endured all sorts of privations, who have refused to be allured by the rewards which reputation and skill would be sure to give them in civil life, are not only kept at a nominal grade, but our legislators have actually conferred on them the special distinction of a law forbidding them to hope for anything higher.

As might have been anticipated, there are vacancies in the medical corps, vacancies which will never, in our opinion, be filled. Young men cannot, will not enter an army in which such a narrow-sighted policy rules; and who can blame them?

We would respectfully call the attention of legislators to the facts in the case, which facts of themselves are the strongest possible proofs of the necessity of

granting the moderate and modest demands of the petitioners. We call upon our readers to favor the measure as an act of principle, resting assured that what they can do for the army surgeon they can do for the profession at large, which he so worthily represents. There can be but one sentiment among the profession in regard to this matter, and let that sentiment be expressed in the shape of appropriate and telling resolutions from all the principal medical associations throughout the United States.

The demands are modest, and are not calculated to infringe in any respect upon the rights of the other corps. The only thing asked for is such an increase in rank and pay as shall be in some way proportionate to what men of equal skill and attainments have a right to expect in civil life.

If it cannot be obtained, let the profession as a body dissuade every promising young man from entering the corps, and let the vacancies in the staff be the argument in favor of a change, when persuasion shall have been used in vain, reason shall have been spent, and further discussion shall have ended.

Reviews and Notices of Books.

LECTURES ON CLINICAL MEDICINE. By A. TROUSSEAU, late Prof. of Clin. Med. in Faculty of Medicine, Paris, etc., etc. Translated from the third revised and enlarged edition by SIR JOHN ROSE CORMACK, M.D., F.R.S.E., and P. VICTOR BAZIRE, M.D. In two vols. Philadelphia: Lindsay & Blakiston. 1873. 8vo, pp. 992.

THE power of imparting instruction, of bringing out the salient points, of impressing upon the learner the particular significance and force of given data, and of explaining in a satisfactory manner the reasons why, very few teachers possess. The particular kind of teaching termed clinical requires this faculty developed to a high degree. That Prof. Trousseau was the leader in this particular branch is now unquestioned. His works upon clinical medicine are now the only remembrances of the power and skill of this great master.

It is useless to attempt a critical review of the work before us, as such would involve a glance over the greater part of the field of clinical medicine. As far as possible the subjects are arranged after a given system, but this arrangement, considering the character of the work and the circumstances under which the lectures were given, could not very well be better. In reading over lecture after lecture, we stand at the bedside of the patient and almost imagine we can hear the voice of the great teacher. The style is colloquial, and consequently entertaining, perspicuous, and impressive. The manner of arranging the different divisions of a given subject for lecture is very methodical, but the rigidity of division is lost in the almost imperceptible gliding of one part into another. The history of disease is full, the detail of symptoms is accurate and exhaustive, and their relations to each other markedly discriminative. In his recital of the phenomena of any disease, or of its treatment, he has the happy faculty of noting an exception to a rule, or of impressing an established principle by the introduction of some

anecdote of his experience, which lightens the dullness of topics into pleasant, profitable reading.

Many subjects which are considered of minor importance by many writers receive from our author very extended consideration; and when we see that these subjects are mostly confined to the commoner diseases, the work becomes of peculiar value to a large class of professional readers. The very fact of Tronseau being an experienced teacher rendered him appreciative of the wants of the general practitioner, and his courteous attention to the little things in the consideration of disease has always been one of his distinguishing features. No one can read his work without being impressed with this fact. As a whole, then, the work has our unqualified recommendation.

THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM 1775-1873. Compiled under the Direction of the Surgeon-General. By HARVEY E. BROWN, Assistant-Surgeon, U.S.A. Washington, D. C. Surgeon-General's Office: 1873. 8vo, pp. 314.

This volume has been prepared for the purpose of giving an authoritative history of the organization of the Medical Department of the Army from the siege of Boston, in 1775, up to the present time. It is divided into five parts: 1. The period of the Revolution; 2. From the close of the Revolution to the reduction of the army in 1821; 3. From 1821 to the declaration of war against Mexico; 4. Commencement of the Mexican war until the bombardment of Fort Sumter, in 1861; 5. From the commencement of the Rebellion to the present time.

Although it would appear that this work was prepared more especially for the medical officers of our army, it is interesting in an historical point of view to every professional reader. The data upon which the history is generalized has evidently been collected with great care, and many extremely interesting points connected directly and indirectly with the earlier officers of the army, especially during the time of the Revolution, are related. The medical officer is so closely connected with the organization, etc., of an army, that the history of the latter becomes a part of his history. The reader who peruses this work will become impressed with the fact, and can appreciate the responsibilities of the Army Surgeon, and the deservedly high appreciation in which he is held by his superiors in command. Notwithstanding that there is an effort to make every statement as concise as possible, Dr. Brown does not lose the opportunity of inserting here and there some extremely interesting historical anecdotes, many of which will be found, as far as we know to the contrary, the first time in print. As a history of the army medical staff it is, as it should be, an honorable record of a noble body men.

SIX MONTHS UNDER THE RED CROSS WITH THE FRENCH ARMY. By GEO. HALSTEAD BOYLAND, M.D., Asst. Surg. Major, Army of the Rhine. Cum, Robt. Clark & Co. 1873, pp. 232.

This is a work which is evidently more interesting to its author than to any one else. We say this in no captious spirit, but merely for the sake of expressing our opinion that the author has made a mistake if he considers his disconnected "jottings" can be woven into a connected narrative by any one but himself. It is nothing more than a personal diary, and as such contains little else than short notes, and very commonplace and unsatisfactory descriptions. As a whole, it gives the reader some idea where the author has been, a very faint idea of what he has seen, and an exceedingly poor estimate of his descriptive qualities.

BODY AND MIND; an Inquiry into their Connection and Mutual Influence, especially in reference to Mental Disorders. An enlarged and revised edition, to which are added Psychological Essays. By HENRY MAUDSLEY, M.D., Fellow Royal Coll. of Physicians; Prof. Med. Jurisprud., Univ. Coll., London. London: Macmillan & Co. 1873. 12mo, pp. 342.

The author has endeavored to step from the somewhat beaten track in an attempt to prove a strictly physiological relation between the mind and body. It is shown, by a very ingenious argument, that the dependencies of mind upon body, and *vice versa*, are so intimate that it is impossible to understand the one without a knowledge of the other. In contradistinction to the purely metaphysical notion of mind, he maintains, by analogical reasoning, that the brain is nothing more than a highly developed nervous centre, the peculiar functions of which hold a similar relation to it, as do the simpler functions to the less significant ganglia. Some very curious facts are related in support of this view.

Having admitted thus much, we are prepared for the deduction that insanity is a derangement of one of the complex functions of the brain, which must be studied in connection with nervous derangement generally; the latter condition, hereditary or acquired, forming the tangible basis of a predisposition to insanity.

The lectures, and also the psychological essays, are confined to this line of argument, and are full of suggestions and ingenious reasoning. The work is written in a charming and elegant style, and of itself, independent of its subject, is worthy of perusal by every one who may be curious to know how much well-chosen language can adorn what would generally be looked upon as an abstruse and heavy subject.

THINKERS AND THINKING. By J. E. GARRETSON, M.D. (John Darby). Philadelphia: J. B. Lippincott & Co. 1873. 12mo, pp. 254.

ANY one who has read "Odd Hours of a Physician," by John Darby, has prepared himself to appreciate the present work; the healthful philosophy of the former gives him a relish for the close and appreciative study of the latter. The style is singularly concise, almost peculiarly so, judging from the latitude which the author has given himself in his previous work. But this terseness is in keeping with a subject in which a more than ordinary care, in the choice of the right words in the right places, is necessary to give a precision to thought. As such, the work cannot be read hurriedly, but with slow and patient thinking. It is only calculated for a certain class of readers who can relish the discussion of the subjects of which the work treats, viz., the great thinkers and their systems of thinking. To such we commend the work as one of singular merit.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Nov. 12, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

(Continued from page 625.)

THE PATHOLOGY OF TALIPES VARUS.

DR. A. B. CROSBY said: I have the honor of presenting to the Society a leg which I amputated three months since, for incurable talipes varus. The patient was a young man, twenty-one years of age, a tinsmith by trade, who had suffered from birth. The patient walked on the outer border of the foot, where there was a large callosity covering the base of the fifth metatarsal and cuboid bones.

He suffered so much pain in walking, from pressure on the filaments of the external saphena nerve, that he voluntarily sought an amputation for relief.

The only interest attached to the amputation was the fact that it was done upon a perfectly healthy man, who was suffering neither from injury nor disease. The patient was therefore treated like a healthy man; after the amputation getting an ordinary full diet, and making an exceptionally rapid recovery.

The specimen presents several points of interest. The atrophy of the foot and leg characteristic of long continued talipes was very marked in this case. It is the theory of the orthopedists that the atrophy, diminished temperature, and cyanotic appearance is due to the bending of the vascular channels out of their natural position, by which both the ingress and egress of blood is much diminished and retarded. In this specimen the anterior tibial and peroneal arteries had eventually become obliterated; so that at the amputation only one vessel required deligation—viz., the posterior tibial.

If, in a case of congenital talipes, the foot is immediately carried into a normal position and retained there, the bent vessels are straightened, and the foot and leg may then be fully nourished, and atrophy avoided. The specimen is also interesting in another connection. It will be seen that the leg and foot have been carefully dissected, so as to show their mechanism. It will be observed that this foot can be both inverted and everted, the former being much the freest motion. A careful examination of the parts in this specimen shows that this lateral motion of the foot occurs between the astragalus and os calcis. The theory, advanced by some, that this lateral motion takes place at the ankle, is shown by this specimen to be incorrect.

The astragalus is so deeply received between the malleoli and so firmly held by the lateral ligaments, that the motions of flexion and extension are alone permitted. The ankle is thus seen to be a purely ginglymoid articulation.

The specimen also shows, that of the twelve muscles passing from the leg to the foot, nine are inserted anterior to the mediotalar articulation. The three remaining muscles, viz., the gastrocnemius, soleus, and plantaris, are all inserted into the tuberosity of the os calcis.

The mediotalar articulation is seen to be very loose, admitting of flexion, extension, adduction, abduction, and a marked degree of rotation. It is at the mediotalar articulation that the distortion of club-foot occurs.

In talipes calcaneus the ankle is in fault, but in no

other variety; and hence the term talipes is a misnomer.

In talipes equinus, the heel seems to be drawn up as though the distortion was at the ankle; but a careful examination will show that the heel is not drawn up, but that the foot anterior to the mediotalar articulation has dropped downward, the result of paralysis of the extensor muscles.

In this specimen there was an equinal element in the distortion; but if the bones of the leg are held in a vertical position, it will be seen that the os calcis is at right angles to the leg, while the anterior part of the foot droops.

It will also be seen that the plantar fascia in this case was much shortened and contracted, by which the antero-posterior arch of the foot has been increased, and a talipes cavus engrafted on the other distortion.

The talipes varus in this specimen was due, as may be seen, to spastic contraction of the anterior tibial, and measurably of the posterior tibial, muscles. The peroneal muscles were manifestly paralytic, and thus the tibial muscles readily rotated the foot inward.

Lastly, the tarsal bones, from continual pressure, have, as may be seen, become permanently misshapen and deformed.

The specimen shows the excellent preservative properties of carbolic acid. The leg was amputated in hot weather; was covered with a roller-bandage wet in carbolic acid, and then rolled up in a newspaper.

Two months and a half later it was unrolled, found in a perfect state of preservation, and the dissection which I have exhibited was made at that time.

CHRONIC PACHYMENINGITIS—HYPOSTATIC PNEUMONIA—OPEN FORAMEN OVALE—CYSTIC, FATTY, AND WAXY KIDNEYS—FATTY AND WAXY LIVER—ACUTE ENTEROCOLITIS.

Dr. HALL presented specimens of the above with the following history:—

Johanna Murphy, *et. sixty-six years*, was admitted to Charity Hospital, August 16th. No previous history of any trouble whatsoever. On admission, complained of severe neuralgic pain in the head; gave potass. bromide, 30 grs. t. i. d. After two days a diarrhoea set in; treated with Squibb's mixture without improvement. In a week dysentery ensued; frequent desire to go to stool, and severe tenesmus and tormina accompanying each action of the bowels; treated with tr. catechu, tr. opii, and mist. cretæ co. Two days preceding death, typhoid symptoms developed; great pain in right iliac region; tympanites, frequent stools; temperature 102½°. Day preceding death, persistent vomiting; tongue coated and dry. Gave creosote, grt. ½ and acid hydrocyan. dil., grt. i. No delirium until three or four hours before death; death from exhaustion.

Post-mortem, twenty-two hours after death: Body medium size, well-nourished; rigor mortis.

Dura mater.—Chronic pachymeningitis (not old). This condition confined to superior portion of dura mater. Some few small hemorrhages between the layers of new formation.

Pia mater.—Some few opacities; vessels dilated, and exceedingly tortuous; considerable sub-arachnoid fluid.

Brain.—Tissue firm; markedly pinkish hue; puncta vasculosa large and numerous.

Vessels.—Present no abnormalities.

Lungs.—Lower lobes of both intensely congested and oedematous; lower lobe, right side, pneumonic process present; surface granular and friable, of a

dark, reddish-gray color, and devoid of air. The upper lobe of this side contained a cheesy mass about ½ an inch in diameter, enclosed within an encapsulating membrane, which membrane contained vessels intensely congested. This caseous mass was situated in an angle formed by the bifurcation of large branches of the pulmonary artery; many small branches could be traced to the encapsulatory membrane, where their calibre was suddenly occluded.

Heart.—Valves appear normal; walls flabby and pale. Upon the surface of left ventricle was a place much resembling an infarction, pale, soft, easily disintegrated, and so much attenuated that the ventricular wall at that place was not more than one line in thickness. The cardiac vessels were examined, but no abnormalities found. The foramen ovale was patent, an aperture about four lines in diameter existing. An attempt seems to have been made to render this opening valvular in character, but when submitted to hydrostatic test this condition was found but imperfectly accomplished.

Aorta.—Was throughout its entire extent in the early stage of chronic arteritis.

Liver.—Enlarged, fatty, and waxy.

Spleen.—Capsule thickened, soft, almost diffident, and intensely congested.

Kidneys.—Small, capsule adherent, nodular; numerous cysts upon the surface. Cortex atrophied; many tubes occupied by urates. Cysts scattered throughout cortex and pyramids. Tubes fatty; vessels of pyramids and Malpighian bodies were waxy.

Bladder.—Normal.

Stomach.—Chronic gastric catarrh.

Intestines.—Present the shaven beard appearance; lower portion of jejunum, the ileum, colon, and the rectum, mucous membrane injected; few small submucous hemorrhages; follicles prominent.

Uterus and appendages.—Large, recent corpus luteum in right ovary; uterus large and congested; mucous membrane of body and cervix intensely congested; a few cicatricial bands at the internal os very much narrowing it, and making it difficult to guide a director into the cavity of the body of the organ.

ABSCESS OF BRAIN—CARIES OF BONES OF MIDDLE EAR—PACHYMENINGITIS—A NEW INSTRUMENT FOR PERFORATING MASTOID CELLS.

Dr. H. D. NOYES.—Patrick Boylan, *et. 45 years*, died August 10, 1873; ward 16; male.

Ante-mortem History.—The patient was admitted May 26, 1873. Received an injury upon side of head three weeks before admission. Complained of severe pain in the ear. After admission had *otitis media*, which soon spread to the mastoid cells. Professor Noyes made an opening into these cells, and allowed the escape of pus. Improvement for a month, when brain symptoms made their appearance. Died August 10, 1873, after being comatose several days.

Post-mortem History.—*Exterior*.—Autopsy made by Dr. Maxwell twenty-nine hours after death: Body large, moderately nourished; rigor mortis marked. An opening about one inch long, parallel with, and about one-fourth inch behind the ear. Both ankles show old fracture; left fibula one and a half inches from malleolus, united at an angle; inner malleolus of right prominent.

Head.—Calvarium normal. Upon exposing the surface of the brain, the vessels of the pia mater were seen destitute of blood; convolutions markedly flattened. The brain was flabby; an abscess opened into the left middle lobe, giving exit to a considerable quantity of thick, greenish pus. Throughout the whole

left hemisphere, at the base, was marked pachymeningitis, and a small, oblong, yellowish-white growth attached to the dura mater, over the outer part of petrous portion of temporal bone. Over this region the membrane was loosened from the bone, and small, scattered growths present. Section of the brain showed pus breaking into the lateral ventricles, destroying the septum lucidum, and entering lateral ventricle of other side (right). The brain bordering it was superficially softened. The primary abscess was situated beneath outer and posterior border of left thalamus opticus. The whole middle lobe and posterior portion of anterior, and anterior portion of posterior lobes—same side—almost diffused, and everywhere the brain-substance was pale and flabby. The petrous portion of temporal bone was removed, and found extensively carious internally; the outer half of inner surface irregular, with several small perforations. Externally—outer surface—the bone showed the perforation made by operation two months ago.

Other organs not examined, friends objecting.

In referring to the operation, Dr. Noyes remarked that he had great difficulty in obtaining a proper instrument, and finally resorted to the use of the pin of a trephine with excellent result. He thought this instrument was peculiarly adapted to such cases, inasmuch as its shape prevented its penetrating the bone farther than necessary; that its edges cut sufficiently well, and the opening which it made was large. Next to this instrument, he thought that a carpenter's reamer might answer an excellent purpose, especially in an emergency.

Aside from the method of operating in this case, the case itself was interesting as showing how long brain symptoms last, and how serious the lesions may be and yet the patient live for the considerable period which elapsed from the time that Dr. Noyes completed his term of service at the hospital, July 31, 1873, up to the time of death.

Dr. Crosby remarked that he had perforated the mastoid process three times. The first case occurred eight years ago. A lady, while on the summit of Mt. Washington, N. H., was suddenly seized with a severe pain in the ear. She was taken to one of the mountain houses, where she suffered more or less for a month, at the end of which time she had a slight discharge of pus from the ear. Dr. C. saw her shortly after this occurrence, and found her with dizziness, headache, and some disturbance of vision. In that case an opening was made into the mastoid cells by means of a gimlet, with good success. The ease with which the operation was performed in this case impressed him with the belief that the gimlet was the best instrument. The second case occurred near Crawford's. A laboring man was attacked with severe inflammation of the ear. Shortly after the attack he proceeded to consult his attending physician; the latter, who knew him well, noticed that he was very unsteady in his gait, and that he was evidently suffering very severely. On examining the patient he discovered inflammation of the mastoid cells. The patient being some distance from home, was sent thither at once; at the same time Dr. Crosby was asked by telegram to see him at once on his arrival. Dr. C. saw him at 1 a.m. the following day. The symptoms were so alarming that he decided to perforate the mastoid at once, which he accordingly did, after placing the patient under ether. The opening was made with the gimlet, when the pus jetted two inches from the wound. All the urgent symptoms were relieved immediately, and the patient made a rapid recovery.

The third case occurred in a medical gentleman,

who, on his way from New York, took a severe cold, as the result of which he had an attack of otitis media. This gentleman having heard of Dr. Crosby's cases, telegraphed to him to come and see him. The symptoms were very alarming, the patient complaining of vertigo, and a sensation as though the bed was sinking from under him. His pulse was rapid, tongue dry, and there were other symptoms pointing toward pyæmia. Contrary to the wishes of a medical friend who was present with the patient, Dr. Crosby perforated the mastoid, and apparently, much to the gratification of said medical friend, no pus was discovered. In the course of twenty-four hours afterwards, pus did escape through the opening made by the operation. The patient ultimately recovered, but the symptoms of vertigo and the sensation of sinking, with sympathetic nausea, remained for a long time.

The medical friend in attendance upon this physician-patient soon after had a similar case. As in the former instance, he did not deem perforation necessary, consequently it was not done. Dr. C. afterwards learned that the whole mastoid process of this patient exfoliated—certainly bad for the patient, but good for the doctor, who refused to have the necessary operation to prevent this result.

Dr. NOYES remarked that Dr. Crosby's gimlet cases were classical, but he should rather object to the gimlet in all cases, as it might with its sharp point penetrate too far.

Dr. CROSBY. It is necessary to know how to use it, and if one knows the anatomy of the parts and exercises due care, no accident need occur.

Dr. NOYES stated that that very matter came up before a recent meeting of the Ophthalmological Society. One of the members of that Society stated that he had examined seven skulls with reference to the anatomical relations of the lateral sinus to the mastoid process, and in all had discovered such thinness of the bony plate, and such a sharpness of curve of the said sinus, as to render it impossible to perform perforation with a sharp instrument without great danger of penetrating too far.

Dr. PUTNAM thought that inasmuch as in Dr. Noyes's case pus had found its way into the ventricles, that hemiplegia and convulsions ought to have occurred.

Dr. LOOMIS referred to a specimen of abscess of brain, commencing with caries of the skull, in which pus invaded the ventricles on the affected side, and in which there were no evidences of paralysis.

RECTO-VENTRAL FISTULA IN A MALE.

Dr. ERSKINE MASON exhibited a specimen of recto-vesical fistula occurring in a man. The patient, aged 27, had enjoyed excellent health until April, 1871, when one night he was seized with pain in the bowels, the whole surface of the abdomen becoming tender, and, according to his account, his bowels were swollen. He was under the care of a Homœopathic practitioner, who told him that he was suffering from peritonitis, for which he gave large injections of castile soap and water, together with five cathartic pills "to move the bowels."

This attack of sickness lasted nine weeks, during which time the patient became very much emaciated. He then resumed his occupation as clerk, and continued at it until Oct., 1871, when he had to cease on account of chills and fever.

In March, 1872, he began to have constant pain over the region of his bladder, attended with diarrhœa, loss of appetite and strength. About this time he came under the care of Dr. Gillette, who very properly diagnosed ulcerated rectum, and gave the appropriate

treatment. Not long after this the patient passed wind through the urethra, and shortly after, faeces.

Dr. Mason first saw the patient in March, 1873, and found him in a most deplorable condition, passing more or less faecal matter through his urethra, and at times unable to void urine at all. Urine would also pass per rectum. For the relief of pain he had been accustomed to take immense quantities of laudanum. Dr. Mason suggested the propriety of performing lumbar colotomy, with the view of diminishing the flow of faecal matter into the bladder. Agreeing to have the operation performed, he was sent to the hospital March 3d. Before he had been in the institution three days his symptoms began to improve wonderfully, his urine commenced to pass clear, and he felt so much encouraged that he left without an operation, and inside of two weeks after admission. He went to the country and continued to improve for a while. Returning from the country, after a fortnight's absence, he was in good condition, and he was advised to have the operation performed at once. He had some business which he wished to settle before he should submit himself to treatment, and the consequence was, he lost a good opportunity. He was not seen again until May 1st following, when Dr. Mason was sent for. The suffering of the patient was then intense; he was writhing in his efforts to pass even a drop of water, the bladder being evidently filled with faecal matter.

For the purpose of having the operation performed the patient was sent to Roosevelt Hospital. He was admitted May 9th. There was then but little hope for him; but as the operation was the only means to afford even temporary relief from suffering, it was accordingly performed.

The operation was performed May 12th. The patient did nicely until the 24th, when he was seized with his old attack of chills and fever. This subsided, however, under the use of quinine, but his condition was too feeble to allow him to rally, and he finally sunk and died June 3d, just twenty-two days after the operation. From the moment the colon was opened, faecal matter ceased to enter the bladder.

At the autopsy the intestines were found bound down in the pelvic cavity. There was a large opening, about the size of the index-finger, opening from the rectum into the bladder. The bladder itself was much thickened, its mucous membrane almost destroyed by ulceration, and the denuded surfaces covered with diphtheritic membrane. There was, besides, an abscess in the prostate. All the other organs of the body were healthy, with the exception of the lungs, the apices of which were seats of the deposit.

Dr. Mason, in speaking of the rarity of the case, remarked that his was the twelfth upon which colotomy had been performed for the relief of recto-vesical fistula in the male, and his case was the shortest time of survival after the operation. The longest time was three years.

Dr. NOYES asked if there was any choice as to the side upon which the operation should be performed.

Dr. MASON said that, with the exception of one case, the operation had always been done upon the left side.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual Meeting and Stated Meeting, Nov. 24, 1873.

Dr. ELLSWORTH ELIOT, PRESIDENT, in the Chair. THE minutes of the annual meeting and of the adjourned annual meeting were successively read and

approved, and on motion the annual meeting was adjourned *sine die*.

Immediately thereafter the stated meeting was opened and the Society called to order.

NEW MEMBERS.

The following gentlemen having been duly recommended by the Comitia Minora, were granted certificates of membership:—

DAVID B. HUNT, 48 W. 36th st., a graduate in medicine at the Col. of Phys. and Surg., Med. Dept. of Columbia Col., in 1870; JOHN G. CURTIS, 35 W. 33d st., a graduate in medicine at the Col. of Phys. and Surg., Med. Dept. of Columbia Col., in 1870; THOMAS A. McBRIDE, 47 W. 27th st., a graduate in medicine at the Col. of Phys. and Surg., Med. Dept. of Columbia Col., in 1871.

STANDING COMMITTEES.

The President announced the following standing committees for the ensuing year:—

Library Committee.—Drs. C. A. Leale, *Chairman*; J. G. Frazer, T. H. Holgate.

Committee on Intelligence.—Drs. F. A. Castle, *Chairman*; L. D. Bulkley, D. C. Carr, W. H. Katzenbach, R. J. McKay, P. B. Porter, Isaac Adler, Eugene Penget, Mary Putnam Jacobi.

Committee on Diseases.—Drs. Charles P. Russell, *Chairman*; George Bayles, A. B. De Luna, Geo. H. Humphreys, T. H. Kellogg, J. V. S. Wooley, Gouverneur M. Smith; and the members of the *Meteorological Committee*, viz., Drs. D. H. Goodwillie, J. W. S. Arnold, R. P. Lincoln, A. B. Judson.

Committee on Finance.—Drs. J. E. Janvrin, E. Bradley, H. P. Farnham.

Committee on Hygiene.—Drs. Moreau Morris, *Chairman*; E. H. Jones, Charles P. Russell, S. A. Raborg. [Three vacancies.]

PRESIDENT'S ADDRESS.

The President remarked that he would not occupy the time of the Society with any set address, as he thought it would be better employed in scientific work; but he wished to thank the members for the great honor again conferred on him.

The Society should congratulate itself upon the success of the past year, over fifty new members having signed its roll during that period. Within the same time the Society had lost, by death, the following members:

Drs. James L. Brown, T. Conant Foster, G. Michelson, Josiah C. Nott, Lewis Tice, Gilbert Totten, Samuel Blois, and A. Clarke Corson.

Another cause for congratulation was, that the past year had been one of peace, the Comitia Minora having had no cases of breach of ethics before it. Difficulties may have occurred, but they have been settled amicably by the parties themselves.

The President also remarked that, so far as lay in his power, the time of the Society should be entirely devoted to science. He referred, moreover, to the pleasant relations sustained with other societies, and hoped to see their officers always present on the platform during the meeting of this Society.

PAPER OF THE EVENING.

A paper was read by Dr. HERMAN KNAPP on "Ophthalmoscopic Optometry," and a discussion followed on the part of Drs. Noyes, Loring, Roosa, and Knapp, relative to the subject of optometry and the history of certain improvements in instruments for this purpose.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 4, 1873.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

The paper for the evening was read by Dr. F. P. Foster, upon

PROPOSITIONS IN REGARD TO ANIMAL VACCINATION.

The remarks which the speaker submitted did not assume the form of a regularly prepared paper, but were presented in the form of propositions, and certain statements in connection with these, which were regarded as essential considerations in connection with the subject of animal vaccination.

The first proposition submitted was as follows:—"Vaccination of the human subject with animal vaccine is attended with a degree of success, as regards the protection of vaccination, equal to that obtained by any other method of vaccination."

The success which has been obtained in England, where the method of vaccination from arm to arm is generally employed, and reported in one of the Blue Books published in the year 1857, has reached 96 $\frac{6}{100}$ per cent. of all the cases vaccinated. The whole number reported was 132,303. Could animal vaccination give any such result as this?

There has been a common opinion in the minds of the profession until very recently, and perhaps to a wide extent still entertained, that such results cannot be obtained by animal vaccination. This opinion may have been founded upon reports made, particularly by English observers, upon this subject, for their reports have been decidedly unfavorable to this method of vaccination. The report made by Dr. Seguin, claiming to present the view taken of the subject in several cities upon the continent, and among them the city of Brussels, stated that success with animal vaccination was very poor indeed, even when conveying the vaccine disease from *one animal to another*; that they were able only to convey it through a series of some half-dozen animals, and then were obliged to obtain a new supply of material for further operation. The speaker was of the opinion that the performance of experiments without obtaining better results than those reported,—they being likewise dependent upon foreign sources for supply of material,—such results could not be fairly held up as a picture of what animal vaccination can accomplish.

During the past three years Dr. Foster has had the opportunity, in connection with the Vaccine Department of the New York Dispensary, to institute and maintain an animal-vaccination service, and he has become cognizant of many thousands of cases during that time. His observations have not been confined to the city of New York alone, but have extended to Boston, Baltimore, and Buffalo. From these cities he presented reports upon 78,176 cases in which bovine lymph had been employed. The results obtained in primary vaccination were generally as follows: In one district 4,793 cases were vaccinated; inspected, 4,322; successful, 4,322; 100 per cent. success. In one district 98 $\frac{3}{100}$ per cent. of cases inspected were successful. In one district 99 $\frac{13}{100}$ per cent. of cases inspected were successful. In this city equally satisfactory results have been obtained as in the other cities mentioned, and in all cases a success equal to any which has been obtained when humanized lymph has been employed, whether the vaccination has been primary or secondary.

The second proposition was: "The vaccine produced by animal vaccination is genuine, and is as thoroughly protective against small-pox as the protection obtained

by the use of any other form of vaccination." The question of protection against small-pox involves two considerations, namely, cases in which small-pox has occurred after using the vaccine matter, and cases in which it has protected individuals exposed to small-pox. With regard to the first, I know of only one case where small-pox occurred after using the lymph furnished by the New York Dispensary. It would not be surprising, however, that cases should occasionally occur. For after any form of vaccination small-pox does occasionally occur. This fact was well known before animal vaccination was instituted; indeed, small-pox itself may occur a second time. French authority was cited in proof of these points.

Dr. De Paul, who introduced animal lymph, has carried his experiments so far as to vaccinate a child, who had been previously vaccinated with animal lymph, with the virus of small-pox, and without communicating the disease to the child. In several instances he reports cases where children who have been vaccinated with cow-pox only, have remained with impunity when one or more variolous patients were in the beds.

The third proposition was: "The use of animal vaccine does not entail the dangers of severe local inflammatory affections, or general febrile complications generally attributed to it by some writers. The dangers or complications are rare. Some unfortunate results have been reported relative to subsequent erysipelatos affections; but the same results have been realized from the use of other virus, and does not hold against animal vaccine alone.

The fourth proposition was: "Animal vaccine, as equal with humanized vaccine, is capable of preservation for a considerable length of time, for transmission to remote parts."

I know perfectly well that, with reasonable limits, the length of time which the animal vaccine can be preserved should be the very least estimate with regard to its liability to produce the vaccine disease. Indeed, I prefer dried lymph, which has been tried and found successful, to that which is much fresher, but which has not been tested. The circumstances under which a calf was vaccinated with matter which had made a double trip across the Atlantic, and had been kept some days after its return, were related. The result of the vaccination was successful in four out of six insertions. The animal vaccine has been sent to Panama, Japan, and other parts equally remote, and successful results have been obtained by the use of the matter after its arrival.

In the case of crusts there is an apparent exception to the truth of the proposition which I have laid down; but crusts are not to be regarded as proper material, so that essentially there is no objection to the statement upon that ground.

The fifth proposition was: "The use of animal vaccine eliminates one of the suspected elements of causing syphilis, and helps to silence the anti-vaccine agitations."

The sixth proposition was: "Animal vaccine is the most trustworthy safeguard for the supply of material in emergencies." In the discussion which followed the reading of the paper,

DR. FIXELL remarked that he regarded one good vaccination as a life-long protection to any individual.

DR. ELLIOTT remarked that his experience in the use of calf, matter entirely corroborated the statements made by the author of the paper. He employs it without hesitation, and has had no failures as yet.

DR. LEAMING mentioned a number of cases which had come under his own observation, where individ-

nals had had varioloid after an apparently perfect vaccination. He also called attention to reports which had been made from the Prussian army upon 51,637 cases of vaccination and revaccination, in whom there were perfect cicatrices, imperfect cicatrices, and entire absence of cicatrices, and in which 64 per cent. were successful. The Doctor urges revaccination as much as possible, basing his recommendation upon such reports and his own experience, believing that only one-third or one-fourth of the cases are protected for life by the first vaccination. By vaccination and revaccination, until it does not take at all, small-pox may be stamped out, and by the use of animal virus it would be a very easy matter to carry the proposition into effect.

Dr. O'SULLIVAN regarded it probable that good success could be obtained with either animal or humanized vaccine; and that, in a great majority of cases, one vaccination probably is sufficient. Still, when epidemics are prevailing, it would be prudent to re-vaccinate, for the reason that revaccination is to be regarded as the only sure test of protection. The Doctor expressed himself emphatically that some unity of action should be taken by the profession in general, relative to giving assurances to the people that there is a protection from small-pox, for such assurance might materially aid in overcoming the prejudice against vaccination, so strong and prevalent in many quarters, especially in large cities.

Dr. CARO remarked that he had always employed humanized lymph in vaccination, and with uniform good success. Upon the 6th of Nov. he applied to Dr. Foster for lymph, and vaccinated a child upon the following day. The reason for vaccinating that child with bovine lymph was as follows: He had vaccinated a child in the same family some time previously, and the pustule had pursued its usual course properly, but when the scab was removed it did not cicatrize well, and left an awkward ulcer. There was no poison in the lymph used, because other persons had been vaccinated with the same material, and no unpleasant results had followed. To convince the parents, however, that the lymph employed in the vaccination of another child was perfectly pure, he had secured some bovine lymph of Dr. Foster, and when he saw that child about seven days after he had performed the vaccination, it was suffering from varioloid in a moderate form, and the parents, as a matter of course, were very angry. The Doctor did not regard his case, however, as a test case for the efficacy of the bovine lymph, but simply regards both of his unfortunate cases as illustrations of what may occur, probably independent of vaccination, in consequence of a peculiar condition of the system, or the operation of some germ-influence, which is developed without reference to vaccination.

Dr. Caro was also of the opinion that there is no necessity for revaccination. It is the custom in *Sicily* to vaccinate at three points in the arm at the first vaccination, and a case of small-pox occurring in an individual who had been thus vaccinated, never had been known upon that island. He had passed through severe and long-continued epidemics, and taken his children with him, who had been vaccinated in this manner, and none of them had taken the small-pox. He does not object to revaccination, but does not regard it as being absolutely necessary. With regard to communicating disease from one patient to another by this means, I have made some experiments, and am fully convinced that it is not possible. I have vaccinated persons from the arms of persons having syphilis, both in its secondary and tertiary forms, without producing any evil results. If the lymph is taken pure, and with-

out blood, there is no reason why it should prove injurious in the way of communicating disease from one person to another.

Dr. JAMES remarked that he coincided with the author of the paper with regard to ridding ourselves of the *liability* of including syphilis or other diseases in performing vaccination by means of animal lymph; but at the same time, when humanized virus is properly taken, the cases in which diseases are included are very rare.

Concerning the relative success of different kinds of lymph, his experience had taught him that this may be materially modified, in reports, by the fact that there are comparatively but few good vaccinators. This is especially liable to be the case in large cities, where large numbers of cases are collected forming bases of reports. In very many instances inexperienced persons are employed to perform vaccination, and the results obtained from such labors may be prejudicial against the success of any kind of material employed.

Dr. FOSTER remarked that he did not regard the results following the vaccination in Dr. Caro's case as being due to the vaccination. The child, perhaps, had been exposed to the effluvia of small-pox before or after the vaccination, and that would account for the appearance of the eruption.

Dr. CARO remarked that all he knew of the history of the case was that the child was in perfect health at the time of the vaccination.

Dr. Lusk remarked that, prior to eighteen months ago, he had been, both from reading and experience—and he saw the first calf brought to Paris for the purpose of introducing animal vaccination—unfavorably impressed with regard to the use of animal lymph. Since that time, however, his success in the use of animal lymph had been entirely different from anything he had previously obtained, and in both primary and secondary vaccinations his success has been absolutely complete. His experience warranted him in saying that revaccination might be successful in those persons who carry perfect scars, and he has also seen persons who had been attacked with varioloid, when there were evidences that a former vaccination had pursued a proper and satisfactory course, leaving perfect scars.

Correspondence.

EPISCLERAL MELANOTIC SARCOMA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the issue of your valuable journal for November 15th, occurs a report of the presentation before the New York Pathological Society, by Dr. H. Knapp, of a case of episcleral melanotic sarcoma. Its interest and value as a specimen depended (as Dr. K. remarked) upon its extreme variety, he never before having seen it in a living subject or in any anatomical collection. His successful treatment in nowise lessens the interest of his report of the case, and reflects credit both upon his skill and the resources of our art in subduing a disease so fatally malignant.

This premises the object of this communication, which is to place on record another instance of this disease, which in history, characteristics, treatment, and results, remarkably and almost completely resembles that of Dr. Knapp's.

Mr. K., aged fifty, of robust constitution, some six years ago first felt a slight pain in his right eye. He then attributed it to a cinder from a locomotive, re-

ceived while riding in a railway-car. No such substance, however, could be discovered. Upon examination, some months later, I found upon the upper and inner margin of the cornea a dusky sub-conjunctival growth extending upwards and towards the inner canthus. From its slight extent, and at that time seemingly trifling nature, it was judged that an application of solid nit. argenti would suffice for its removal. This treatment resulted only in the discovery that a removal of the growth followed each application, and that the disease was really advancing. I then advised that Dr. Asa Horr, of Dubuque, Iowa, be consulted. After careful examination, Dr. Horr attempted its removal by the knife. The same results again followed. In spite of the most careful and repeated dissections, it was found that the growth was slowly but surely extending. This plan was then abandoned, and the malignant nature of the disease (before suspected) now became quite apparent. The patient was now advised that extirpation of the globe was the only resource. At this time the tumor was quite dark, of a wedge shape, the thicker portion overlapping the cornea from the upper border so as to preclude vision. Aside from its history and color, it bore a resemblance to a pterygium. Numerous practitioners failed to make a satisfactory diagnosis, and the case acquired a considerable local notoriety from its unique character. At this period, by the advice of a friend, the patient placed himself under the care of a distant surgeon, who extirpated the globe. Some months after his return, my attention was called to a small bluish tumor, of the size of a grain of corn, hard to the touch, and situated upon the inferior surface of the supra-orbital plate. This was at once removed, and a thorough destruction made by caustic of the adjacent tissues. Nearly a year has now elapsed, and a complete cure seems assured. There can be no doubt of the identity of the disease described by Dr. Knapp and the one here reported. In fact, with little modification, Dr. K.'s description would apply to my case. In view of its malignant character, its disinclination to invade the deeper tissues of the globe is, perhaps, worth noting. The result also verifies the opinion of the distinguished oculist who reported its duplicate, viz., that enucleation is the only method of insuring the safety of the patient, and that delay is fraught with danger.

II. C. MARKHAM, M.D.

Medical Items and News.

PROF. LOUIS J. R. AGASSIZ, the distinguished savant, died in Boston, Mass., December 14, 1873, in the 67th year of his age. He was born at Orbe, in Waillande, May 28, 1807. He studied at the gymnasium at Biel, afterwards at the Academy of Lasanne, subsequently at Heidelberg and Munich, where he obtained the degree of doctor of medicine. In 1839 he published a work on the Natural History of the Fresh-water Fishes of Europe, also Researches in Fossil Fishes, descriptive of Echinodermes. His studies of the Glaciers, wherein he promulgated a new theory, did more to make his reputation as a scientist than any other of his productions. For some years he filled a chair in the scientific department of Harvard University.

In 1865 Prof. Agassiz organized an expedition to Brazil, for the purpose of examining the valley of the Amazon, obtaining further evidence in regard to his glacial theory, and obtaining specimens and information. The expenses of this expedition, which comprised some eight or ten persons, were defrayed en-

tirely by private liberality. The success of Agassiz during this expedition was unbounded. Hundreds of new varieties of fish were discovered and specimens obtained. His reception by the Emperor of Brazil, himself a very scientific man, was flattering in the highest degree.

In the latter part of 1871, Prof. Agassiz, with the aid of some wealthy students of science, equipped an expedition for the purpose of examining the constitution and character of the ocean bottom. The work of investigation was continued until July, 1872. Subsequently Mr. Anderson presented him with the island of Penikese, on which to found a school of natural history, which school has now suffered such an irreparable loss in the untimely death of its master.

DR. W. C. ROBERTS, Vice-President of the New York Academy of Medicine, died in New York Dec. 9, aged 64.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from December 5, 1873, to December 18, 1873.

GHISELIN, JAMES T., Surgeon.—Granted leave of absence until June 6, 1874; and his resignation accepted to take effect June 6, 1874. S. O. 245, A. G. O., Dec. 10, 1873.

BAILY, JOSEPH C., Surgeon.—Relieved from duty in Department of California, to proceed to Baltimore, Md., and, on arrival, report by letter to the Surgeon General.

CALDWELL, D. G., Assistant Surgeon.—Assigned to duty at Fort Griffin, Texas. S. O. 222, Department of Texas, Dec. 6, 1873.

DE WITT, C., Assistant Surgeon.—Granted leave of absence for four months. S. O. 241, A. G. O., Dec. 4, 1873.

KIMBALL, J. P., Assistant Surgeon.—Assigned to duty at Fort Randall, D. T. S. O. 266, Department of Dakota, Nov. 28, 1873.

CAMPBELL, A. B., Assistant Surgeon.—To report in person to the Commanding General, Department of Texas, for assignment to duty. S. O. 247, A. G. O., Dec. 13, 1873.

PATZKÉ, J. II., Assistant Surgeon.—Assigned to duty at Fort Fetterman, Wyoming Territory. S. O. 182, Department of the Platte, Dec. 3, 1873.

BOOKS RECEIVED.

MEDICAL LEXICON : A Dictionary of Medical Science, containing a concise explanation of the various subjects and terms of Anatomy, Physiology, Pathology, Hygiene, Therapeutics, Medical Chemistry, Pharmacology, Pharmacy, Surgery, Obstetrics, Medical Jurisprudence, Dentistry, etc., with the accentuation and Etymology of the terms and the French and other Synonyms. By ROBEY DUNGLISON, M.D., LL.D., late Prof. Inst. Med., etc., Jefferson Med. Coll. A new Edition, enlarged and thoroughly revised by RICHARD J. DUNGLISON, M.D. Phila. : H. C. Lea, 1874.

VICK'S ILLUSTRATED FLORAL GUIDE FOR 1874. James Vick, Rochester, N. Y.—One of the evidences of the progress of the times and of the vast scale on which business is carried on in these days, may be seen in the costly elegance with which trade catalogues are now gotten up, and Seedsmen and Florists excel in the good taste they display in this line, and prominent among them is the annual above named.

Original Lectures.

INFANTILE SPINAL PARALYSIS.

A LECTURE DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK. *

By E. C. SEGUIN, M.D.,

NEW YORK.

(Reported by FRANK P. KINNICUTT, M.D.)

GENTLEMEN:—I think that you may obtain a clearer idea of the importance of infantile spinal paralysis if we study it not separately, as I had at first purposed we should, but as one of the forms of paralysis to which infants are liable. At a subsequent meeting we can briefly inquire into the other varieties of infantile palsy, and you will then obtain a knowledge of a great part of the nervous pathology of infancy, and be better prepared to diagnose the most important of these affections—infantile spinal paralysis. The period of life termed infancy is that which includes the first dentition to the beginning of the seventh year. The pathology of this stage of existence is treated of separately by authors, in part because of the peculiar difficulties in diagnosis presented by children of this age, and in part because of numerous peculiarities they exhibit, such as susceptibility to the action of causes of disease, of medicines, and the exaggeration of certain groups of symptoms, such as the spasmodic element in the sphere of the nervous system. There is no essential difference, please remember, between infants and adults in the nature, course, and treatment of disease.

The following synopsis represents the principal forms of paralysis which are likely to occur in infancy, together with their leading pathogenetic factors:

PARALYSIS IN INFANCY.

1. HEMIPLEGIA (clot, injury, embolism, tumor in brain).
2. PARAPLEGIA (injury, clot, inflammation of cord).
3. PERIPHERAL PARALYSIS (compression, etc., of nerve-trunk).
4. INHIBITORY PARALYSIS (peripheral irritation).
5. INFANTILE SPINAL PARALYSIS (atrophy of motor nerve-cells).

The last of these is the disease we shall study to-day, and several examples of it are before you, affecting subjects of different ages. The term which I have adopted is one of numerous synonyms by which the disease has been known. The first systematic writer upon the subject, Heine, used a corresponding German name, *spinale Kinderlähmung*, in his second edition of 1860. French writers upon the diseases of infancy, who studied the subject very thoroughly in its clinical aspects, Rilliet and Barthez,* denominated the disease *paralysie essentielle de l'enfance*. Bouchut, entertaining a very singular notion of the pathology of the affection, gives it the name of *paralysie myogénique*. Niemeyer retains the term essential paralysis, considering it as a safe one to adopt during the present unsettled state of opinion upon the question of pathology. The word *essential* is used by these authors as equivalent to functional, or *sine materia*. The title infantile paralysis is one employed by such authors as C. B. Radcliffe and Adams. Duchenne, in the last edition of his work on electrization, calls the disease *paralysie atrophique de l'enfance*, instead of *paralysie atrophique graisseuse de l'enfance*, as in his edition of 1860. Hammond, in his

treatise upon Diseases of the Nervous System, speaks of organic infantile paralysis.

SYMPTOMS AND COURSE OF THE DISEASE.

In brief, infantile spinal paralysis may be defined as an acute febrile affection, resulting in generalized paralysis, which shortly disappears from all but a limited part of the body, where the akinesis persists indefinitely without impairment of sensibility, is accompanied within a few weeks by atrophy of the palsied muscles, and is followed later by various deformities,—the result of altered balance of power at certain joints. The anatomical lesion of the disease consists in primary (?) atrophy of the nerve-cells of the anterior horns of the spinal cord (motor tract), and in secondary (?), complicating (?) myelitis.

There are three quite distinct stages in the course of infantile spinal paralysis.

(a) *The Febrile Stage*.—A child, and usually a healthy or even a robust child, has an indisposition, with febrile movement, evidenced by restlessness or drowsiness, hot skin and frequent pulse. The mother's attention is often called to a co-existing local affection, such as indigestion, intestinal catarrh, or morbid dentition. The last is the usual condition referred to, because the age when infantile spinal paralysis is most apt to occur (six to twenty-four months) includes nearly the whole period of dentition, and because mothers as well as many practitioners are only too willing to hold the teeth responsible for any disease which may arise during their evolution. The fever has not, to my knowledge, been studied with the thermometer. Fever has been observed in nearly all cases* (forty out of fifty). When parents assert that no fever was present at the outset, it must be borne in mind that a certain degree of intelligence is required to enable a person to recognize fever; that in some cases only skilled observations (thermometrical measurement) will reveal its existence; and that it may have been present for a few hours only. Besides these phenomena, there are several nervous symptoms present in a certain proportion of cases, convulsions usually not involving the facial muscles, and delirium. Hyperæsthesia is also present; but whether this is a true hyperæsthesia, or an evidence of that morbid sensitiveness which is part of the febrile state, remains uncertain.

(b) *Stage of Paralysis*.—As the fever subsides, the mother, upon handling the child, discovers that voluntary motion has been lost in nearly the entire body. The exact period when the akinesis appears, and whether it develops slowly or suddenly, are points not yet investigated. The paralysis is at first generalized, often involving all the limbs, very rarely the face. At the same time no impairment of sensibility is to be noted. In a short time, a few hours, the paralysis recedes from some parts and persists in others; it being very rare that more than one-half of the body remains palsied. This retrocession of the paralysis, its disappearance from some limbs, and fixation upon one or two, or upon unsymmetrical distant muscles, is highly characteristic of the disease—I might almost say pathognomonic. This fixation is usually upon parts of the lower limbs, more seldom upon the upper, and rarely upon parts of the trunk. In only one case has a muscle of the head been found definitely paralyzed—the temporal. The muscular group which is most often affected is the anterior tibial and peroneal. Owing to the immunity of the abdominal muscles, the bladder and rectum perform their functions.

* On Nov. 8th, 1873.

† Rilliet et Barthez, *Maladies des Enfants*, t. II., p. 545 et seq. Paris, 1861.

* Laborde. De la paralysie (dite essentielle) de l'enfance. Paris 1864, p. 3.

(c) *Third Stage*.—Inseparably connected with the definitive akinesis is the muscular atrophy, with loss of electro-muscular contractility, and with deformities. The loss of irritability in the palsied muscles, as tested by the electrical current (faradic), occurs very early—at a period varying from one to six weeks. In one case atrophy and loss of electro-muscular contractility were well marked on the fourth day (Laborde *). A very few years ago three observers independently made the very valuable observation that these atrophied muscles could be made to contract by the application of the galvanic current. Mr. Harry Lobb,† Dr. William A. Hammond,‡ and Mr. J. Neftin Radcliffe§ (from 1863 to 1865), are each entitled to the merit of making this observation in infantile palsy. The application of this reaction to the galvanic current for prognosis will be stated further on.

The atrophy of the muscles is both relative and positive, and is accompanied by certain histological changes, which will be detailed when we study the morbid anatomy of the disease. In the case now before you, a young man, seventeen years old, in whom infantile palsy set in at the age of twenty months, the bones of the legs, themselves much reduced in size, seem covered only by skin and a little adipose tissue. These legs also exhibit two accompaniments of the atrophy of infantile spinal paralysis, viz., imperfect circulation and diminished temperature. The atrophied parts are very purple, and are quite cold to the touch. The diminution of temperature has been measured by Heine,|| and found very great; the atrophied region in one case having a surface temperature of only 14° Réaumur (63°·5 Fahr.). This is in striking contrast to the temperature of limbs palsied by a cerebral lesion.

In consequence of this akinesis, indefinitely prolonged, accompanied by wasting of the muscular tissue, there are formed a number of *deformities*. Some of these consist merely in arrested development, as indicated by the shortening of the affected limb;—there occurs a relative atrophy. This shortening of a limb, a lower limb more especially, gives rise to secondary deviations in form, such as twisting of the pelvis and lateral curvature of the spine. These secondary deviations, which are the result of attempts to restore disturbed equilibrium, are called compensatory. It is important to distinguish these compensatory deformities from the primary, or truly paralytic ones, because the treatment of either kind differs radically. The positive deformities are caused, as stated in the definition, by impairment in the balance of muscular power about any articulation. For example, in the feet of one of the patients before you, you see an example of deformity which constitutes the talipes equinovarus of surgeons; toes point downward and inward. The anterior and posterior muscles of the legs are palsied and atrophied, and consequently the feet obey the laws of gravity, dropping into their position because the ankle-joint is well back upon the posterior third of the foot. There is no resistance to passive movement in all directions. In other cases only one set of tibial muscles is paralyzed, and the deformities are produced by the unchecked (unantagonized) action of the healthy muscles. In the feet we may thus have talipes equinus ("the most common and important variety," Erichsen), or talipes equinovarus, or

any of the varieties which you will find fully described in surgical text-books. In a case of talipes equinus of this sort we find great resistance to any attempt at overcoming the deformity; the tendo-Achillis is very tense. The muscles governing the movements of the knee-joints may be paralyzed, and in consequence we obtain analogous deviations at that joint. About the upper extremities the deformities are less striking, but are produced by the same double mechanism, obedi-ence of parts to gravity, and unchecked action of certain muscles. The spinal deformities are nearly always of the compensatory sort: for instance, a shortened leg necessitates the inclination of the pelvis to the side on which the shortening is; and in order to preserve the equilibrium of the body, the lumbar vertebrae bend so as to form a concavity on the opposite side, and higher up there occurs a secondary spinal curve to the side of the shortened limb. The lateral curvature is known technically as scoliosis. This is rarely due to palsy of spinal muscles, though I have now under treatment a case of this primary paralytic scoliosis. A variety of muscular disorders may cause scoliosis in individuals not affected with infantile paralysis. (Consult the various works on deformities.) Other spinal deformities, more often primary, are the bending forward of the spinal column, non-angular, called kyphosis; and the bending backward, termed lordosis. The bending forward is shown in a minor degree (quasi-pathological) in what is termed stooping—a supposed sign of studious habits. Lordosis, as first clearly pointed out by Duchenne, may be due to palsy of the abdominal muscles, or to bilateral palsy of the lower spinal extensors; in both cases the upper part of the body is thrown unnaturally backward to preserve equilibrium. The two forms may be recognized without a minute examination of the seat of palsy, by using a plumb-line. Dropping the line from the shoulders, it will clear the sacrum in cases of lordosis due to palsy of the erectors of the spine; whereas in palsy of the abdominal muscles it will fall within the sacrum. In the latter case there is a deepening of the normal lumbar curve without positive backward projection of the upper part of the body.*

One word more concerning the genesis of primary deformities. It is often said that in club-foot and other deformities, the efficient cause of the deviation is spasm of the preponderating muscles. This I believe to be extremely rare, and a belief in this erroneous doctrine leads to insufficient (merely orthopedic) treatment of the deformities.

Changes in nutrition in the paralyzed parts; many of these, as observed in the disease, consist in what may be termed relative atrophy, i.e., arrested development or retarded growth, e.g., diminution in the calibre of the blood-vessels, not only of the parts affected, but extending further into the vessels above the atrophied muscles, and even into the main trunks. In a certain number† of cases of atrophied lower extremities, a marked diminution in calibre has been found to exist in the ilia, and even in the lower portion of the aorta. In the boy before you, with extreme atrophy of all the muscles below both knees, the whole vascular system of the lower extremities is abnormally small. It is necessary to bear in mind that no pathological change is discoverable in the walls of these vessels; it is an excellent example of simple arrested development. Again, we find the bones of the impli-

cated regions diminished in size, the arrested development affecting rather their circumferential than their longitudinal growth, only a slight shortening being found to exist even in cases of long standing.—Let us now devote a few moments to the study of the more positive changes in nutrition, as exhibited in the muscles. The morbid anatomy of the muscular system in infantile spinal paralysis has been the subject of laborious and careful investigation, and the results of the latest researches tend to convince us of the existence of different kinds of muscular degeneration, though by no means of equally frequent occurrence, in this disease. By far the most common form is: (a) the simple atrophy, a form which almost always affects such muscles as are kept in forced repose for a long period; it manifests itself in a shrinking of the individual muscular fibres; a transverse section reveals the separation of the contractile substance proper from the sarcolemma; moreover, as a rule, we find a fatty infiltration of the cells of the connective tissue. (b) A granular degeneration is described as succeeding in order of frequency. In this form proteinaceous granules (bodies unaffected by ether, dissolved by acetic acid) are found in the fibre itself; the striation disappears gradually, more slowly than in the simple atrophy; as in the latter form, a fatty infiltration of the interstitial tissue also exists. (c) A true fatty degeneration is believed to be comparatively rare. The earlier belief, that it constituted the peculiar muscular lesion in infantile paralysis, aside from its occasional occurrence, may have arisen from the almost unexceptional co-existence of the interstitial fatty changes with the forms above described.

Pathological Anatomy.—We have now to consider the morbid anatomy of the disease itself. By the earlier writers it was believed to be essentially functional in its character. The first step toward giving us a clearer conception of the true nature of the affection was made by Heine, who published the results of his observations in 1840; discarding the functional theory, he expressed his belief that the disease was due to a violent congestion, with perhaps a subsequent inflammation of the nervous centres. Later, cases were published by Laborde and Cornil, in which a sclerosis of the antero-lateral columns was described. In an autopsy by Echeverria, sclerosis and amyloid degeneration of the antero-lateral columns, sclerosis of the anterior nerve-roots, and brown pigment in the nerve-cells, were found. In a case of von Recklinghausen's, tubercular deposit was discovered in the substance of the cord. H. Roger and Duchenne, Jr., reported two cases in which autopsy revealed atrophy of the anterior and antero-lateral columns, diminution in size of the nerve-fibres, increase of the interstitial connective tissue, and the presence of numerous amyloid bodies. In an *unrecognized* case of infantile paralysis, Mr. J. Lockhart Clarke, of London, described an atrophy, a degeneration of the cells of the anterior horns.

To Prévost (a pupil of Charcot's), therefore, is due the credit of first recognizing this cell-degeneration as the true lesion in this disease. In 1866 he published the report of the autopsy in which this lesion was discovered; since that date a number of cases have been reported by Charcot and his pupils, in which a similar cell-degeneration has been found. Studied with the microscope, we find that it consists in an increase of the normal pigment of the nerve-cells; the latter are observed to become densely packed with pigment-granules; and finally, to wholly lose their cell character. In their place a simple granular mass, which gradually undergoes a marked diminution in

size, is seen. In a certain number of cases no granular change is discoverable, the cells seemingly being subjected to a simple wasting process.

Other morbid changes, indicating a myelitis, have been described as among the lesions of infantile paralysis, e.g., a sclerosis, an increase of the interfibrillar connective substance of the medullary columns, with a marked increase in the nuclei of that substance; the formation of cavities in the gray matter, apparently through a process of liquefaction; small clots in the same substance; corpora amylacea in both the gray* and white matter; and finally, what can only be described as condensed patches of tissue in the former.

The question is yet disputed whether the granular cell-degeneration is to be regarded as the primary lesion. The fact that in one case at least† the cell-lesion has been observed without any concomitant myelitis, would seem to support Prof. Charcot's view that the cell-degeneration is the primary and essential lesion. This is further strengthened by the recent revelations concerning the state of the nervous centres in progressive muscular atrophy; in that disease the cells of the anterior horns being found in part or wholly destroyed by a similar pigmentary degeneration, without surrounding myelitis.

Prof. Charcot was so kind as to give me some sections of the cord from the case, now classical, which he published under his own name and Joffroy's (his interne) in 1870. I will pass around two microscopes armed with half-inch objectives, one showing a transverse section of a normal spinal cord, the other the section from Charcot's case. Both sections are from the mid-dorsal region of the cord, a part in which the anterior horns are small and the cells few. The normal anterior horn exhibits six or eight large well-defined multipolar ganglion-cells, stained red by carmine, their nuclei standing out more deeply tinged than the body of the cell. On the other hand, careful examination of the morbid section shows nothing but a somewhat condensed gray horn-tissue, without one distinct ganglion-cell. The granulations which probably once existed in the place of some of the cells have been dissolved by the method (Clarke's) used in preparing the section. I would also call your attention to the fact, that the diseased anterior horn is shrunken and less club-shaped than the same part in the healthy section.

The DIFFERENTIAL DIAGNOSIS of this from other paralytic affections of infants I leave until our next meeting, when we shall review the whole group briefly.

The PROGNOSIS of infantile spinal paralysis is not good, for many reasons. The disease is a severe one, accompanied by a serious central lesion, and is possibly incurable in a certain proportion of cases in spite of every favoring circumstance. Then, usually we are consulted weeks, months, and even years after the stage of atrophy and deformity has set in, and the cure is then more questionable in proportion to the period of time which has thus elapsed. Many of the deformities can be remedied, at any age, by proper orthopædic treatment; but that is not curing the disease. Until the recent (see *supra*) discovery of the re-action of atrophied muscles we had no guide in prognosis beyond time, and the appearance of the parts. Now we know that if any contraction can be obtained by means of the galvanic current (interrupted), there is some hope of restoring the muscles to activity.

* The theory now gaining ground in regard to the character of these bodies is, that they are due to an amyloid degeneration of the round cells of the neuroglia.

NOTE.—Dr. Albutt's case (*Lancet*, 1870, II, p. 84), I reject because of evident traumatism.

One authority (Dr. Hammond)* says: "If the muscles can be made to contract with either the induced or the primary currents, the cure is merely a matter of time and patience;" but I am afraid that this is rather a sanguine expectation. I should give a very guarded prognosis, under these circumstances, in all cases having lasted beyond a year.

I will be very brief about the treatment. The management of the first or febrile stage is a matter of uncertainty; few practitioners see the cases in this stage, and when they do, the diagnosis of simple fever, or of fever symptomatic of some teething or intestinal disorder, is usually made. Were I to meet with such a case, and have due reason, from occurrence of delirium, convulsions, and the presence of hyperæsthesia, to suspect impending spinal palsy, I should leech the child's spine, and apply counter-irritants to the extremities. Besides, treatment indicated by the state of the mouth or bowels should be carried out. The treatment of the second stage is likewise a matter about which no rules based on solid experience can be laid down. I should favor irritating the spine and the extremities, keeping the child's bowels free, and applying electricity, in either of the forms commonly employed, to the palsied muscles.

The management of the third stage may be divided into (a) the treatment of the central lesion and of the atrophy; and (b) the curing of the deformities.

(a) We know no means which will with certainty remedy the central lesions which I have described as existing in this disease. Strychnia and nux vomica were prescribed by Meine and by other older authorities, but are now abandoned. The hypodermic injection of strychnia about the wasted parts has been recommended of late, and is worthy of a trial; from $\frac{1}{100}$ to $\frac{1}{16}$ grain may be injected with safety, according to the age of the patient. Of course everything which shall tend to improve the patient's general condition (hygiene, nutritious food, cod-liver oil, exercise) will favor the reconstruction of the atrophied nerve-cells. The means of treating the palsy and atrophy consisted, until a few years ago, in the (nearly always vain) application of the faradic current, cold and hot douches, and the systematic friction of the atrophied muscles. These last are valuable, especially the alternate use of ice (or cold water) and hot water to produce hyperæmia. Beyond these in value comes the use of the galvanic current, which will in many cases produce good contractions in the wasted muscles. The number of cells to be used must be determined by trial, 10—20—30 elements of Stöhrer's battery, may be required to obtain a reaction. The positive electrode should be placed upon the nerve-trunk supplying the atrophied group of muscles, and the negative sponge upon various muscles of the group; the current being meanwhile interrupted slowly by removing and replacing the negative electrode, or (to produce maximum irritation) reversed as well as interrupted by a mechanical contrivance on the battery or in the hand. I would suggest the use of nitrous-oxide gas for the purpose of avoiding the intense pain produced by a large number of cells. Especially is anesthesia useful in first examinations when you want to base a prognosis upon the result. An advantage offered by the use of this adjunct is, that the child being still, you are able to recognize a small muscular contraction which might be overlooked during the struggles of the suffering patient. How difficult it is to be sure that contractions occur under these circumstances, those of you who have attended in the electrical room of the Col-

lege will remember. I am led to make a remark which I should have made when speaking of the prognosis, to the effect that a safe negative prognosis cannot in my opinion be based upon a first or second galvanic examination. If you can afford the time, and your patient the money, you should ask for a number of trials, at least six, before saying that the patient cannot be cured or improved. A great difficulty in the way of proper and successful galvanization consists in the very common stretched state of the atrophied muscles. For instance, in a palsied leg with healthy posterior tibial muscles, there exists a pes equinus, and in consequence the wasted anterior tibial muscles are stretched to a great degree. Now, gentlemen, I believe that this tense condition will prevent galvanic reaction for a long time, if not indefinitely; and the relief of the tension either by a mechanical contrivance (shoe), or better still by a tenotomy and a shoe, is followed by success in treatment. In illustration I would cite a private case of my own, a lady suffering from symptomatic muscular atrophy consequent upon cerebro-spinal meningitis, in whom the muscles of the legs were in much the same state as the muscles in cases of infantile spinal palsy; the posterior tibial muscles having in part recovered. The anterior tibial muscles were kept tense by a strong pes equino-varus, and for several months careful galvanization (even electro-puncture) produced no reaction. At last, as a *dernier-recours*, I asked Dr. H. B. Sands to cut the tendo-Achillis in both legs and to put the limbs in plaster-of-Paris. This was most dextrously done, and four days after the tenotomy distinct contractions appeared under galvanization in the atrophied muscles.

The muscles, after improving in size under the above means, gradually begin to obey the will, and also respond to the faradic current. This stage in recovery should be carefully looked for, and the change of current made.

The indications for tenotomy and for mechanical treatment of the deformities are various, and really out of my province. You would do well to call in the aid of a surgeon skilled in the devising of apparatus, and make use of the instrument as auxiliary means in promising cases. The most important use of tenotomy I take to be that referred to above, facilitating the galvanic treatment. Incurable cases, and cases in which only slight improvement can be hoped for, had better be at once sent to an orthopædic surgeon for advice and treatment.

The foregoing table of autopsies, in cases of infantile spinal paralysis, may prove useful. I believe it to be quite full.

EMPHYSEMA OF POST-CLAVICULAR SPACE.—Dr. G. H. Butler, of New York, reports a case of rupture of a bronchial tube attending an acute bronchitis, and occurring during an attack of coughing. The patient, a female, aged 55, large and fleshy, showed the emphysema, the result of the rupture, in the post-clavicular space. The treatment for the emphysema consisted in a compress. Recovery good.

VENTILATION IN OUR SCHOOLS.—The subject of ventilation in our schools is being pretty thoroughly discussed in the daily papers. A remedy is sought for the evil. We believe now, as ever, that medical inspection will be the first step in the proper direction.

CHARITY HOSPITAL, NEW YORK.—Dr. H. Knapp is Visiting Ophthalmic Surgeon to this institution, *vice* Dr. H. D. Noyes, resigned.

* A Treatise on Diseases of the Nervous System. New York, 1871, p. 692.

Original Communications.

OPHTHALMOSCOPIC OPTOMETRY, AND DEMONSTRATION OF A NEW OPHTHALMOSCOPE.

By Dr. H. KNAPP,

SURGEON TO THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE,
AND OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK.

(This paper was read before the Medical Society of the County of New York, on November 24, 1873.)

WHEN I selected the subject for this paper, I had, at first, some misgivings whether it could be made sufficiently attractive for a medical audience not specially engaged in the culture and practice of ophthalmology. In an interview with which our esteemed President honored me, I could recognize, through the veil of his exquisite politeness and professional courtesy, that he shared my feelings. Yet the subject is not without importance, and, though not entirely new, still too little appreciated, not only by the profession at large, but even by, I dare say, the majority of ophthalmic practitioners. A steady attendant of the meetings of the Medical Society of the County of New York during the last five years, I could not fail to witness that any subject, however remotely connected with the science and art of medicine, found an appreciative and indulgent audience if it had some claims to novelty and practical importance. When a paper was less favorably accepted and less generously commented on, not the special nature of the subject seemed to be the cause, but want of novelty and thoroughness.

The ophthalmoscope is no longer an instrument in the hands of specialists only. The number of general practitioners who have learned its application and employ it with benefit in the diagnosis of various diseases is daily increasing. A comparatively new field is its use as an optometer; that is, (1) *the determination of the refraction of an eye independently of the statements of the patient*; and (2) *the determination of the location and size of morbid conditions or products in the interior of the eye*.

I will illustrate my subject by examples, and, in analyzing them, show the *object*, the *importance*, and the *method* of ophthalmoscopic optometry.

Two weeks ago a lady brought to me an orphan-boy, eight years of age. She stated that she was one of the visitors of the Asylum, and that the boy had not advanced in his instruction on account of bad sight. She had his eyes examined in an ophthalmic hospital, and was told that the deficiency of vision was caused by a "wasting away of the optic nerves," and that nothing could be done for it. Fearing, on the strength of this statement, that the child was threatened with blindness, she wished to have my opinion on his eye-disease. He could readily make out middle-sized print, but small print appeared indistinct to him, and the longer he tried to read, the more indistinct the print became. At distance he read Sn, XL. With the ophthalmoscope I saw a well-marked crescent around the optic disk, so common in near-sighted eyes, but no other abnormality. Testing his refraction with the ophthalmoscope, I found, not myopia, but hyperopia, the degree of which was $\frac{1}{10}$ in either eye. With +10 or +12 glasses his vision showed the normal acuity both for distant and near objects. The lady bought the boy a pair of spectacles, which removed all his trouble. She brought him to me again two days ago, stating

that he is now able to go along with his class in his instruction, and seems quite another child.

This case is by no means uncommon, and shows the advantage of possessing a method of ascertaining objectively the state of refraction of the eye. The boy was too young for giving relevant answers on functional examination of his organs of vision.—From many examples I beg to select and relate the two following:—

Two twin brothers, aged six years, of Mannheim, Germany, physically and mentally well developed, were brought to me by their—wealthy and ambitious—parents, who stated the boys did not learn to read, pretending that they were unable to see the letters clearly enough to distinguish them from one another. The parents had never seen any disease in the eyes of the boys, nor had they noticed any deficiency of sight in their plays and movements. On ophthalmoscopic examination I found the four eyes sound, but hyperopic of $\frac{1}{2}$. I ordered them convex spectacles No. 6, and neither parents, children, nor teachers complained afterwards.

A still more remarkable case came under my care while I was residing at Heidelberg.

A student of law, 20 years of age, wanted to have his eyes examined. On inspection they showed nothing extraordinary, but when I asked him to read he held the book so close to the eye that the nose slid over the paper along the lines he was reading. His cornea was not an inch distant from the letters, and when he had read a short time the tip of his nose was black. He read fluently, however, and seemingly without an effort. In this way he had gone through all his studies. Once he had consulted a celebrated oculist of the modern school, but had neither learned in what this peculiar defect of his eyes originated nor how it could be amended. On examining him I found that he easily read finest print when pressing the book against his nose, and letting the light fall in from the temple. Looking at remote objects, he half closed his eyelids, and even thus could count fingers at the distance of about eight feet only. In every respect he made the impression of an excessively near-sighted person. All concave glasses, however, from the weakest to the strongest, were rejected as making his sight worse. Examining him with the ophthalmoscope, I found the refractive media, inner coats, and optic disks in normal condition, but hyperopia $\frac{1}{2}$ in one eye and $\frac{1}{3\frac{1}{2}}$ in the other; the highest degrees of that anomaly ever observed in eyes possessed of their crystalline lenses. The degree of hyperopia, as found with the ophthalmoscope, was confirmed by the ordinary test-glasses. With spectacles +4 he fluently read finest type at the ordinary distance, and his far-vision was excellent. He ever after wore his glasses with the greatest comfort, and his prospects for the future were no longer clouded by an unbecoming and embarrassing infirmity. But what trouble, annoyance, and mockery he might have been spared had the nature of his eye-disease been sooner detected!

In determining the existence and degree of myopia, the ophthalmoscope may be very useful, though this error of refraction is less likely to be overlooked than its opposite condition, hyperopia.

I will try, Mr. President and gentlemen, shortly to explain the method of determining ametropia, *i.e.*, errors of refraction, with the ophthalmoscope. You all know that ophthalmoscopic examinations are made according to two methods: that in the direct or upright and that in the inverted images. The examination in the upright image only is available for the de-

termination of the anomalies of refraction. If the background of the eye be illuminated by the reflector of the ophthalmoscope, the illuminated portion of the background becomes a luminous body, sending forth rays of light in every direction. A portion of these rays find their way through the pupil and cornea into the air. The course they pursue depends on the location of the luminous part of the background, and the refractive powers of the crystalline lens and cornea. In emmetropic eyes, *i.e.*, eyes of a normal refraction, the background emits rays which leave the cornea as parallel, provided that the eye examined makes no effort of accommodation. An emmetropic observer, intercepting these rays with relaxed accommodation, can bring them to a focus on his own retina; that is, he receives a distinct image of the background of the examined eye. If the patient is near-sighted, the rays emerge convergent from his cornea, and unite in a point at a finite distance before his eye. The situation of that point depends on the degree of his near-sightedness. The physician may intercept these rays by a concave glass, which renders them parallel and then brings them to a focus on his own retina. The problem is to find the proper glass. If we can place behind the ophthalmoscope a series of concave lenses, ascending successively from the weaker numbers to the stronger, looking constantly with relaxed accommodation, the image of the background, indistinct at first, will become clearer and clearer, until one auxiliary glass makes it perfectly distinct. *The number of this glass, to which, of course, the distance of the glass from the eye has to be added, indicates the degree of myopia.*

A similar procedure determines the degree of hyperopia. The background of hyperopic eyes, lying in front of the posterior principal focal plane, sends forth rays which emerge divergent from the cornea. Placing convex auxiliary glasses behind the ophthalmoscope, and advancing from the weaker to the stronger numbers, we determine the degree of hyperopia by the strongest positive glass that gives us a distinct image of the fundus. The distance of the glass from the eye, in this case, is to be deducted from its number.

Thus we can determine the state of refraction of any eye. I mention again, that both the physician and the patient must keep their accommodation relaxed during the examination. The physician will learn to do this by imagining that the ophthalmoscopic image is far away, and the patient will relax his accommodation by gazing vaguely at a distant object, or staring into vacancy. If the physician himself is near-sighted or hyperopic, he must take the error of refraction of his own eyes into account, or place behind the mirror another glass, which renders his refraction normal.

The second object of ophthalmoscopic optometry is the determination of elevations and depressions in the background of the eye.

Last week a patient 56 years of age was sent to me by a prominent oculist of this city, who wished to have my opinion on the rather critical case of the gentleman. The sight in one eye was perfect, but only $\frac{1}{20}$ of the normal standard in the other. There were no symptoms of cerebral disease, none of external abnormality in the eye itself. Both globes had apparently normal tension, and the pupils responded quickly to light. The field of vision was complete in either eye. The decline of visual acuteness in the one eye had been gradual for some months. With the ophthalmoscope I found incomplete excavation of both optic disks, in its appearance unmistakably glaucomatous. The completeness of the visual field in both eyes, especially in the bad one, was the only feature that made me hesitate to declare the disease simple, *i.e.* chronic glaucoma,

and advise iridectomy. Suspending my judgment, I ascertained the shape and depth of the excavation, and found to my surprise that the excavation from the deepest part of the optic disk to its margin was greater in the good eye than in the bad, namely, 0.91 mm. in the former, and 0.63 mm. in the latter. The shape of the excavation differed in the two eyes; in the good, the walls of the disk slanted down gradually; in the other, abruptly. The excavation in the good eye, therefore, was conical, as we see it in physiological conditions, or in atrophy of the nerve; in the bad eye it was cupped, as in glaucoma. The blood-vessels in the former were bent at the margin of the papilla; those of the latter partly bent and partly interrupted. The main trunks of the blood-vessels in both papillae were crowded towards the nasal wall, but did not reach it, approaching, however, nearer to it in the bad than in the good eye. These conditions led me to the belief that chronic glaucoma probably existed in the bad eye, and a tendency towards chronic glaucoma also in the good. The incompleteness of the excavation, and the preservation of the field of vision, determined me to advise a further observation of the case. If the excavation should increase both in latitude and depth, the diagnosis of glaucoma would be confirmed; otherwise a gradual atrophy, incapable of being arrested by an operation, must be assumed.

Some among you may, perhaps, think that this whole statement betrays pedantry in diagnosis and pusillanimity in therapeutics. What harm is done, it may be said, by the excision of a piece of the iris? Little, in the majority of cases. But suppose the experiment, whether iridectomy is useful or not, had to be tried on your own eye: would not you like your oculistic adviser to note down the depth of the excavation, and measure it again four or six weeks hence?

Besides depressions, there are *elevations* in the interior of the eye, caused by exudations, tumors, protrusions of the coats, etc., the measurement of which may be of great diagnostic and prognostic value. How many cases of cerebral disease show a swelling of the optic disk and its vicinity. To determine the height of such a swelling, and to follow its increase or decrease, is not only of the greatest importance for our judgment on the preservation of sight, but on the nature and course of the intracranial affection. The method of ascertaining the relief of the background of the eye is only a repetition of the determination of the state of refraction. The optical constants of different eyes varying but little, we may consider them as known quantities, and determine the location of any point of a physiological or pathological part, with reference to the posterior principal focal plane of the eye. As in hyperopia the retina lies in front of that plane, in myopia behind it, elevations on the background of a normal eye will be determined with convex auxiliary lenses, depressions with concave ones. It is easy to understand that the higher the degrees of hyperopia or myopia, which correspond to certain elevations or depressions, the farther from the posterior principal focal plane are the points to which such degrees of hyperopia or myopia relate. Their location can be calculated, and furnishes the basis for the determination of the relief of the fundus oculi. Suppose the crest of a choked optic papilla shows hyperopia $\frac{1}{2}$ its base emmetropia; then we know that rays which fall upon the cornea with a convergence of n'' , are united on the crest of the tumor. n'' and the distance of the crest of the choked disk from the second principal plane of the eye, which distance may be called x , form two conjugate focal lengths, of which n is known by ophthalmoscopic investigation, and x can be determined by calculation, according to the

general formula $\frac{F_1}{f_1} + \frac{F_2}{f_2} = 1$, $f_1 = n$, and is positive

in myopic, negative in hyperopic eyes. $x = f_2 = \frac{n F_2}{n - F_2}$

F_1 and F_2 denote the first and second principal focal lengths of the eye: $F_1 = 15$ mm., $F_2 = 20$ mm. If x is $< F_2$, the point in question is situate in front of the posterior principal focal plane; if $x > F_2$, the point lies behind it. For the sake of convenience of calculation, the formula above mentioned may be somewhat altered, as Helmholtz has shown in his *Physiologische Optik*, p. 49. $n - F_1$ means the distance of the anterior conjugate focus from the anterior principal focus. $x - F_2$, which we may call l_2 , means the distance of the posterior conjugate focus from the posterior principal focus. If we deduct F_2 from both sides of the above equation, viz.: $x - F_2 = \frac{n F_2}{n - F_1} - F_2$, and

reduce the equation, we obtain $x - F_2 = l_2 = \frac{F_1 F_2}{n - F_1}$

l_2 means the distance of the point under examination from the posterior principal focal plane. This point lies in front of the posterior principal focal plane when l_2 is negative, but behind it when it is positive.

I have calculated a table showing l_2 corresponding to the different degrees of H or M, as ascertained with the ophthalmoscope, and shall publish it in the second number of the third volume of the Archives of Ophthalmology and Otology.

If we have determined the distances of the basis and apex of a diseased part from the posterior principal focal plane, we can, by addition or subtraction, easily find their distance from each other. In this manner the height of elevations and the depth of depressions can be measured.

This method of determining the relief of the background of the eye was first described by myself at the *Congrès International d'Ophthalmologie de Paris* in Aug. 1867, and published in the Transactions of that society, page 165, etc., "*Sur la mensuration ophthalmoscopique des élévations du fond de l'œil.*"

A year later Mauthner described it in his exhaustive treatise on Ophthalmoscopy, Vienna, 1868, and after him, Dr. E. G. Loring, in an excellent paper on the *Determination of the Optical Condition of the Eye by the Ophthalmoscope; with a new Modification of the Instrument for that Purpose*. *Am. Journ. Med. Sciences*, 1870, p. 323, etc.

From the foregoing remarks, it is clear that we must have an ophthalmoscope at our command that admits of a complete series of auxiliary lenses to be placed behind it. Liebreich added five lenses to his mirror, and placed them in a fork-like holder.

More than ten years ago I had a small trial-case made for the purpose of determining the refraction of the eye with the ophthalmoscope. Dr. H. D. Noyes enlarged the holder for the auxiliary lenses, fitting it to the glasses of the large trial-cases of spectacles.

Rekoss, of Koenigsberg, placed behind the mirror a rotating disk containing a small number of correcting lenses. E. G. Loring availed himself of this contrivance in an excellent manner. He inserted 23 lenses in three disks, which could separately be placed behind the mirror. This was a great improvement on the former instruments. Yet the frequent change of the disks was found laborious.

H. Cohn, of Breslau, put the same number of glasses into one disk, but his instrument appears inconvenient on account of its size, the disk having a diameter of three inches.

I then had the ophthalmoscope made which I

placed before the American Ophthalmological Society at Newport, last July, and which I beg leave here to demonstrate.

It consists of the ordinary mirror, having a central perforation of $3\frac{1}{2}$ to 4 millimetres in diameter. (See Fig. 1.)

FIG. 1.

Behind the mirror are two disks, which contain the following auxiliary lenses, both convex and concave: 2, 3, 4, 6, 8, 10, 12, 14, 17, 20, 24, 33, 48—the convex lenses being inserted into the upper disk, the concave

FIG. 2.

into the lower. (See Fig. 2.) In order to obtain a greater number of glasses, the margins of the disks

overlap each other behind the opening in the mirror in such a way that each convex glass can be combined with each concave glass. For the weak numbers, from 8 to 48, such combinations are hardly ever required in practice; but for the stronger numbers they are indispensable. The glasses can be changed without removing the instrument from the eye. The disks are enclosed between two metal plates, which prevent the glasses from being easily soiled. Fig. 3 shows the

in the mirror. The glasses of each row can be changed without removing the instrument from the eye.

About six weeks ago I received the September number of *Zehender's Klin. Monatsblätter*, which contains a drawing and a short description of a new ophthalmoscope by *Dr. L. De Wecker*, of Paris. In this ophthalmoscope 24 auxiliary lenses are inserted into the marginal portion of a disk, which is turned behind the mirror by means of a cog-wheel and a stem. I immediately

FIG. 3.

A1

posterior surface of the instrument, with two objective lenses.

Through the small openings in the cover, above and below the central perforation, the number of the auxiliary lenses is read. The posterior plate can be removed whenever it is necessary to cleanse the glasses, which may be about once a month.

To use the instrument conveniently, I have arranged a table which shows the most suitable combinations, representing, in near approximation, the numbers of spectacles contained in our ordinary trial-cases. Furthermore, I have calculated the shortening and elongation of the optical axis corresponding to each convex and concave glass. A third table refers to aphakial eyes, *i.e.*, eyes in which the crystalline lens is absent. These tables will be sold with the instrument, and may be hung up in the ophthalmoscope room for reference whenever we want to determine the location of any object in the background of the eye. The measurement of the height of an elevation or the depth of a depression requires no more than the ophthalmoscopic determination of the location of the two remotest points of the morbid parts, and the addition or subtraction of their corresponding values as found in the table.

Since I exhibited this instrument at Newport, *Dr. Loring* has devised a very elegant modification of his previous instrument. He has inserted into one disk all the numbers that were formerly contained in the three disks. The disk of his new instrument has two rows of glasses, each of which, by shifting the disk up and down, can be conveniently placed behind the aperture

ordered the instrument, but have not yet received it. If the drawing represents it in its natural size, the hole in the mirror has a diameter of 1.5 mm. only, and each of the lenses has a diameter of 2.5 mm. These dimensions are surprisingly small. To test the availability of this and similar instruments, I have tried to determine, by experiment, how far the size of the opening in the mirror can be reduced. I had a series of mirrors made, in which the diameter of the opening varied between 1 and 5 millimetres. The results of these experiments, thus far, have been as follows: The greatest brilliancy—intensity of illumination—of the ophthalmoscopic image is obtained by an opening in the mirror of $3\frac{1}{2}$ to $3\frac{3}{4}$ millimetres. If we further reduce the opening, the image becomes proportionately darker.

Openings larger than 4 millimetres in diameter render the image likewise darker, by the fact that they cast a shadow in the centre of the ophthalmoscopic field of vision.

The small openings have still another disadvantage: they act as diaphragms, cutting off the peripheral rays, and thus do not readily indicate whether the adjustment of the ophthalmoscope by means of the auxiliary lenses is accurate or not. As the correctness of the observation depends on the nicety of this adjustment, ophthalmoscopes with small apertures in the reflector are of little service for optometric purposes. They are bad instruments altogether, because they throw a great amount of light into the patient's eye, but intercept so many of the returning rays that the physician obtains a dark image. If there were no

limits in the smallness of the opening in the mirror, the problem to add the necessary number of auxiliary lenses would be simple. Thinking that an opening with a diameter of 3.75 millimetres was the most appropriate, I distributed the auxiliary lenses to two disks, and by making the edges of the disks overlap each other behind the aperture in the mirror, obtained a series of lenses as extensive as pathological or physiological research seems ever to require. The instrument, with regard to brilliancy of the image and accuracy of optometric determinations, is, it seems to me, equal to the best ophthalmoscopes; whereas with regard to completeness and cleanness, it may, perhaps, have some advantages of its own.

Mr. President and gentlemen: I have ventured to appear before you with a specially ophthalmological subject. If I have not succeeded in engaging your interest for it, I have to accuse myself alone, for the subject would have been worthy of an abler advocate. It is certainly a triumph of medicine to possess the means of detecting, without asking the patient one question, in an anomalous refraction of the eye, the cause of his inability for work, and almost constant headache; and in detecting the cause, we have at the same time found the remedy which cures him from weakness and pain. Furthermore, it is gratifying enough to gaze through the ophthalmoscope on the varied and brilliant pictures of the interior of the eye, and to study them both for their own sake and their connection with general diseases. When, moreover, in the advancement of science, we look no longer on these changes as mere flat pictures, but measure their height and depth to a small fraction of a millimetre, on a field in which, only two decades ago, their reigned impenetrable darkness, then we have passed the lower forms of the qualitative analysis, and arrived at the quantitative. And so, as this field has been gloriously conquered, the whole vast expanse of medicine will, in the long lapse of ages, be cultivated and raised to the dignity of exact science. But since it has to be conquered step by step, I thought it might not be asking too much of a general medical society to lend at times an indulgent ear to the specialist, the small freholder who ploughs but one acre.

Progress of Medical Science.

THE OLEATES OF MERCURY.—These new mercurial preparations, which are being used so extensively and with such success, were first introduced to the profession by Mr. John Marshall.

In a practical and extremely valuable paper on this subject, he says that the oleates are cleanly and economical, and have a much greater diffusibility or penetrating power than the old mercurial ointments, for they are absorbed by the skin with remarkable facility, and manifest the remedial effects with great promptitude. They are not to be rubbed in, like ordinary liniments, but should be merely applied with a brush, or be spread lightly over the part with one finger, otherwise they may cause unnecessary irritations. This result, however, may be obviated by the addition of a small quantity of olive oil or purified lard, according as an oleaginous or an unctuous preparation is required. In his experience, however, the addition of morphia was a great advantage, but it was necessary to use the simple alkaloid, as neither the hydrochlorate, the acetate, nor the meconate are soluble in oleic acid. For every drachm of the solution of oleate of mercury in oleic acid, one grain of morphia is to be added. As a rule, from ten to

thirty drops are sufficient for one application. This should be repeated twice daily for four or five days, then at night only for four or five days, and afterwards every other day until a cure is obtained. Unless used in excessive quantities, the oleate does not salivate or produce any marked constitutional disorder. In regard to the applicability and utility of the oleates Mr. Marshall says they seem to be specially designed for persistent or chronic inflammations, provided only that the seat of the disease be in or near to the skin. As to the preparation of this remedy, he adds: "The oleate must be prepared with the oxide precipitated by caustic potash or soda, from a solution of the metal in nitric acid recently made and well dried. The solution of mercury by oleic acid is assisted by a temperature of 300° Fahr. The 5 per cent. solution is a perfectly clear, pale yellow liquid, resembling olive oil, but thinner; the 10 per cent. solution is also fluid and perfectly clear, but as dark as linseed oil; whilst the 20 per cent. solution is an opaque, yellowish, unctuous substance, closely resembling in appearance resin ointment, melting very readily at the temperature of the body, and forming a kind of transparent, viscid, colorless varnish when applied to the skin. The chief care to be observed in the manufacture of these solutions is not to hurry the process, and not to employ a high temperature, or the mercury will be immediately reduced."

In cutaneous diseases the 5 per cent. solution, without morphia, is recommended. It has been found particularly serviceable in syphilis menti. In congenital syphilis a piece of the 20 per cent. ointment, about the size of a pea or a bean, may be placed in the child's axilla night and morning for five or six days, and without any sign of uncleanness, produces constitutional effects. As a topical remedy for certain local manifestations of syphilis, such as the non-ulcerating forms on the head, face, and neck, the 10 per cent. solution is a valuable adjunct to other treatment.

DIAGNOSIS OF EARLY PREGNANCY.—Among other valuable papers read at the recent meeting of the British Medical Association, was one by Dr. Rasch, in which he called attention to an important symptom of early pregnancy, which had never before been mentioned by the leading obstetrical authorities.

After detailing the principal symptoms which are to be found in the text-books, Dr. Rasch said that no opinion should be expressed in any case unless the uterus had been made out beyond doubt by the bimanual examination. The vaginal examination should always be made by two fingers, unless circumstances forbade it, as by so doing results much more accurate could be obtained. An enlargement found, the distinction had to be made between enlargement by hypertrophy or by tumors, and enlargement by pregnancy. To solve this difficulty, the author has continued his investigation in a very large number of cases, of which he kept notes for nearly ten years, and enlarged experience has fully borne out what had helped him in making a few times a right diagnosis where better men had failed. This important symptom was fluctuation. That it must be felt very early seemed to him, *a priori*, certain. The best way to feel it was to introduce two fingers into the vagina, while the other hand steadied the womb through the abdominal walls, and alternately to manipulate the uterus with the two fingers. In some part of the uterus the fluctuation would be found often in one corner of the fundus, sometimes lower down. In most cases of early pregnancy the author found the uterus anteverted, and then the manipulation was more easily done than when the womb was retroverted. At first it

was usual for fluctuation to be felt only by the fingers in the vagina, sometimes, too, by the outer band at the same time. After three months, it would be mostly felt by outward manipulation alone, but we should never trust to that only. The catheter should always be introduced when accurate results were desired.

ANTIDOTE TO PHENIC ACID.—The poisonous effects of phenic acid are due to the acid itself, and not to the alterations to which it is subject.

Mr. Husemann has proved, by numerous experiments, that the alkalies and alkaline earths are true antidotes to this acid, while the fat oils, glycerine, etc., are entirely without effect.

In cases of poisoning, it is necessary to use these antidotes in large excess and in solution, the saccharate of lime being employed successfully. This is obtained, as is known, by dissolving 16 parts of sugar in 40 of distilled water, and adding 5 parts of caustic lime. Digest for three days, stirring from time to time, filter and evaporate to dryness. The product thus obtained constitutes the saccharate of lime; it dissolves easily in water.—*Journ. de Pharm. et de Chim.*, Sept. 1873.

ACTION OF FRESH CHOLERA DISCHARGES UPON ANIMALS.—An interesting series of experiments with the discharges from cholera-patients was made during the latter part of July, of this year, by Andreas Högges, of the University at Pesh, a report of which is published in the *Centralblatt für die Med. Wissenschaft.*, No. 50. The points which it was sought to determine were, in brief, the following:

I. Do fresh cholera discharges operate injuriously upon the organism of lower animals, and under what manifestations?

II. Does an artificially excited catarrh of the stomach and bowels increase the susceptibility to the action of the cholera discharges?

III. Can a current of air bear away particles from the discharges, which are capable of affecting the organism injuriously, and what difference is there in this respect between non-disinfected and disinfected cholera discharges, simple diarrheal discharges, and putrefying fluids?

IV. Are cholera discharges freed from their form-(living) elements still able to act upon animals?

V. What portions of the disinfected or non-disinfected discharges does the air-current bear away, and what is the further destiny of these form-elements when they fall upon a neutral medium or one adapted to their development? In what manner do these elements modify the action of this medium?

To decide the first and second questions, fresh cholera discharges were given to healthy dogs and to others, in which an artificial catarrh of the stomach and intestines had been excited by the administration of croton-oil, sulphate of copper, etc. Both dogs were made sick, with frequent vomiting and diarrhoea. But while the previously healthy animals recovered in three or four days, those in which a catarrh had been excited died the day following.

To determine the third question, rabbits were placed under a bell-glass and exposed to air which had become impregnated as desired, from either cholera discharges, disinfected or not disinfected, diarrheal discharges, or putrefying fluids. Two rabbits, in one of which a bronchial catarrh had been produced by inhalations of ammonia, were exposed for twenty-four hours to air from cholera discharges not disinfected.

On the third day following, violent purging set in, and both animals became soon cold and collapsed. The one in which a bronchial catarrh had been excited died first, and the other five hours later. A rabbit

exposed for twenty-four hours to air from disinfected cholera discharges remained well. Another, exposed for an equal length of time to atmosphere impregnated from simple diarrhoea-stools, escaped uninjured, while another, which remained for twenty-four hours in atmosphere contaminated from putrid fluids, though at first made insensible, afterwards recovered without harm.

As to the fourth point, cholera discharges were injected into the jugular veins of dogs and guinea-pigs, the discharges in one case having first been freed from their form-elements by thorough filtration, and in the other not. The effect in both instances was the same.

To determine the final points, a current of air was made to pass through fresh cholera discharges, both disinfected with carbolic acid and not disinfected, and then conducted through two separate vessels, which contained, respectively, an indifferent fluid-medium, and one adapted to the support and development of any living forms which the current should bring to it. The two fluids used were distilled water and the fluid of Cohn. In a short time, in the fluids communicating with the undisinfected discharges, a considerable number of form-elements had accumulated, which proved to be, almost exclusively, the bacteria which are usually found in putrid animal fluids. In twelve hours Cohn's fluid had become clouded and milky; in twenty-four hours it was covered with a thick bluish-green fungous slime, and emitted a foul odor. The distilled water remained clear. Both these fluids, when injected into the veins of dogs and rabbits, caused the same symptoms as after injection of the cholera discharges themselves. This was also true of the fluid of Cohn, after its fungous elements had been quite removed by filtration, showing that these elements are, at least, not the only source of infection. Similar experiments with discharges which had been disinfected with carbolic acid, showed that the organisms which the air-current brought to Cohn's fluid were incapable of propagation. Upon injection of the distilled water and fluid of Cohn, after previous disinfection of the discharges by carbolic acid, only symptoms of carbolic-acid poisoning were manifested.

PROFESSOR ZEISSL ON THE TREATMENT OF SYPHILIS.—After some experimental treatment of syphilis in its various manifestations, Zeissl expresses the following conclusions:

"The preparations of iodine judiciously administered, with the appropriate regimen, are able to cause the disappearance of the first manifestations of syphilis, or, at least, to so modify the disease that it yields to a small number of mercurial inunctions, without a subsequent recurrence of relapses, that is, so that the syphilis may be regarded as definitively cured." He further observed that the initial appearances succumbed sooner to an early mercurial course than to the iodine treatment. While the later phenomena quickly disappeared under iodine, the initial indurations resisted longer. The affections of the mucous membranes, as papules upon the tongue, and in the whole region of the mouth and pharynx, yielded much earlier to the treatment with iodine, at the most necessitating occasionally a slight cauterization, while with mercurial treatment they persist for a longer time. Instead of the iodide of potassium, the following formula was employed, on account of its greater cheapness:

R. Tinc. iodinii.....	3 ss.
Aque fontis.....	3vj. M.
S. A tablespoonful at morning and night.	

Moreover, the tincture of iodine seemed to show a much less tendency to cause acne or coryza.

The writer further observes that syphilis in pregnant women, especially where the infection has occurred at conception, is more rebellious than in women not pregnant. It will not usually disappear before delivery of the fetus, and it is always necessary to continue the treatment at the expiration of pregnancy.

Iodiform is much used by Zeissl, locally for indolent ulcers of the skin, and internally, in doses of from 2 to 3 grains for syphilitic neuralgia. It is given in pill, with some bitter extract. For the gangrenous buboes which occur in syphilitic patients, especially in hospital practice, nothing was found equal to the continual water-bath. He found the actual cautery in these cases much less serviceable. He would supplement the old adage: *Quod ferrum non sanat, ignis sanat* with *Quod ignis non sanat, balneum continuum sanat*.—*Wiener Med. Wochens.*, 46.

A SUCCESSFUL CASE OF ABDOMINAL SECTION FOR INTUSSUSCEPTION.—At a meeting of the Royal Medical and Surgical Society, in Nov., Mr. Jonathan Hutchinson narrated a case in which he had successfully opened the abdomen for the relief of intussusception. The patient was a child aged two years. The intussusception had commenced at the cæcum, and was of such length that its extremity, presenting the inverted ilio-cæcal valve, was extruded several inches at the child's anus. The condition had been one month in course of development; latterly the case had been treated as one of prolapsus, and attempts had been made to keep the bowel in place by means of a cork pad. The child was very ill, and the author having failed in attempts to effect reduction by enemata, etc., and having had experience of several similar cases which had ended fatally, determined to operate. The child was put under chloroform, and the abdomen was opened in the middle line, below the umbilicus. The intussusception was then easily found, and as easily reduced. The after-treatment consisted only in the administration of a few mild opiates, and the child made a rapid recovery.

The author next narrated briefly the particulars of three somewhat similar cases in which he had been consulted, and in which the intussuscepted bowel could be easily felt by the finger in the rectum. In all three, in spite of persevering treatment by injections, bougies, etc., the patients had died unrelieved.

Without attempting anything like a statistical analysis of recorded cases, the author appended to his paper, in tabular form, the notes of a very considerable number of cases bearing upon the diagnosis and treatment of similar lesions.

From the consideration of these the following conclusions were suggested:

1. That it is by no means very uncommon for intussusception to begin at the ilio-cæcal valve, and to progress to such a length that the invaginated part is within reach from the anal orifice, or even extruded.

2. That it is of great importance in all cases of suspected intussusception to examine carefully by the anus.

3. That in almost all cases of intussusception in children, and probably in most of those in adults, the diagnosis may be made certain by handing the invaginated part through the abdominal wall.

4. That the prognosis of cases of intussusception varies much; first, in ratio with the age of the patient, and secondly, with the tightness of the constriction.

5. That in a large proportion of the cases in which children under one year are the patients, death must

be expected within from one to four or six days from the commencement.

6. That in the fatal cases death is usually caused by shock or by collapse from irritation, and not by peritonitis.

7. That in many cases it is easy, by estimating the severity of the symptoms (vomiting, constipation, etc.), to form an opinion as to whether the intestine is strangulated or simply irreducible.

8. That in cases of strangulated intussusception, whilst there is great risk of speedy death, there is also some hope that gangrene may be produced, and spontaneous cure result.

9. That in cases in which the intussuscepted part is incarcerated and not strangulated, there is very little hope of the occurrence of gangrene, and it is probable that the patient will, after some weeks or months, die, worn out by irritation and pain.

10. That the chances of successful treatment, whether by the use of bougies, or by the injection of air or water, are exceedingly small, except in quite recent cases, and that if the surgeon does not succeed by them promptly, it is not likely that he will succeed at all.

11. That the cases best suited for operation are those which have persisted for some considerable time, and in which the intestine is only incarcerated; and that these cases are also precisely those least likely to be relieved by any other method.

12. That in the cases just referred to, after failure by injections, bougies, etc., an operation is to be strongly recommended.

13. That the records of *post-mortems* justify the belief that, in a considerable number of the cases referred to, the surgeon will encounter no material difficulty after opening the abdomen.

14. That the circumstances which might cause difficulty are—(1) the tightness of the impaction of the parts; (2) the existence of adhesions; and (3) the presence of gangrene.

15. That in selecting cases suitable for operation, the surgeon should be guided by the severity of the symptoms to an estimate of the tightness of the strangulation, and as to the probability of gangrene already set in.

16. That in cases in which the patient's symptoms are very severe, or the stage greatly advanced, it may be wiser to decline the operation, and trust in the use of opiates.

17. That the operation is best performed by an incision in the median line below the umbilicus.

18. That in cases of intussusception in young infants (under one year of age) the prognosis is very desperate, scarcely any recovering excepting the few in whom injection treatment is immediately successful, whilst a large majority die very quickly.

19. That the fact just mentioned may be held to justify, in the case of young infants, very early resort to the operation.

20. That it is very desirable that all who, in the future, have the opportunity for *post-mortem* examination of intussusception cases, should give special attention to the question as to whether an operation would have been practicable, and should record their results.

TO INCREASE THE GROWTH OF BONES.—M. Ollier read a paper recently on this subject, supporting his statements by experiments and clinical observations. He finds that where there has been an arrest of growth of the long bones, impeding progression or producing deformity, he can induce growth by producing a superficial exfoliation of bone by means of caustics.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, January 15, 1874.

THE NEXT MEETING OF THE STATE SOCIETY.

THE coming meeting of the Medical Society of the State of New York will naturally call the attention of members and delegates to some questions of importance which should come up for consideration. There is no doubting the fact that a great interest is manifest throughout the State in the success of this organization, and that there is a disposition to aid it in all endeavors to make it thoroughly representative. Although as a State Society it ranks all the others throughout the country, there are yet many changes to be made in its management before it can best serve the interests of the profession of the State.

The election of permanent members, being one of the peculiar features of the organization, has from the time the Society first existed claimed a good deal of attention, and the abuses connected therewith, as well as the remedies suggested, have been pretty freely discussed. It has always been considered an honor to gain the position of Permanent Member, more probably for the reason that such a position is hard to obtain, than for any very special privileges which may belong to the office. The difficulties in the way of a choice of but one or two members each year, from a very small number of districts, have been, on general principles, no easy task to overcome, and the dissatisfaction of the unsuccessful candidates, always in the majority, no more than can be expected.

The very difficulties in the way of a choice have stimulated ambitious and pushing candidates to use strategy rather than trust to the governing influences of ordinary justice in the selection. There must always be disappointment and complaint on behalf of unsuccessful candidates; but it should be the aim of such as have the best interests of the Society at heart

to reduce the murmurings to the minimum. The first step in this direction is a strict impartiality in the selection of the Nominating Committee.

As at present managed, there is too much danger that not only the permanent membership, but all the other offices of the Society, may be under what in political parlance is styled a "ring" influence.

The responsibility of appointing the Nominating Committee rests entirely with the President, who, with the best intentions, is too apt to follow a time-honored custom of making his selection from a very small list. The consequence is, that we find the same gentlemen on this committee from year to year. We have all along contended that this should not be, and that the time has come when a change should be made, if for no other than the appearance which such a custom assumes of being partial, and the ultimate danger of establishing a centralization inimical to individual rights and common justice. There should always be representative men from the different districts to compose this Nominating Committee, and this could be accomplished without being compelled to narrow a selection to a few of the former Presidents.

A good plan would be to make selections from the prominent officers of the different County Societies. The very fact of their holding such positions proves their right to be representatives. Such gentlemen, too, would be acquainted with the wants of the members of their Society, and could vote intelligently upon the different candidates. All other things being equal, such a vote would naturally be given to one who has been the longest eligible.

Another plan was proposed at the last meeting, which is a good one, and if it could be made to work, would guarantee, if possible, a better choice. This proposition comprises the formation of a committee of delegates from each district, which committee shall elect one of its number for the Nominating Committee. This suggestion cannot, however, be carried out at the next meeting, for the reason that it would involve an alteration in the by-laws. All we have to hope, however, is, that the President will be more than ordinarily careful in the selection of the Committee, and will use his best exertion to secure the co-operation of good and fresh men. This being done, the duty of the Committee should be to give the preference to those in a given district who have waited the longest for it.

The publication of the Transactions by the Society should be another matter worthy of thoughtful deliberation. The opportunity to declare an independence of legislative favor will be a good one, even if by the majority it may be considered that the virtue has become a necessity. We hope that there will be no two opinions regarding the policy to be adopted, viz., the independent publication by the Society of its proceedings from this time forth. The volumes could then be issued in a creditable shape, and in a reasonable time after the annual meeting. The best men of the Society

are in favor of it, and now is the time to take a decided stand. The expense of the undertaking will not be burdensome if each County Society follows the example of our own in agreeing to pay its share.

It is becoming more and more the general opinion of the profession that very little can be gained in furthering professional interests by appeals to Legislatures. The experience of the State Society in this respect is particularly suggestive, and all the deductions are strongly to endorse such an opinion. This fact deserves to be taken into consideration in connection with the time the annual meeting is held. This particular season was agreed upon principally, if not solely, for the reason that the Legislature met at the time, and it was considered to be of the greatest possible convenience and utility to have the suggestions and recommendations of committees attended to at once. As we are beginning to believe that legislation does us but little good, is it worth while, because the Legislature is in session during the worst season of the year, to sacrifice every other interest of the Society to such a consideration? At the last session, the practicability of changing the time of meeting to the early fall came up for discussion, and the committee to whom the matter was referred reported favorably. For some reason or other no action was taken. We hope at the next meeting the question will again come up, and be decided in the affirmative. There is, in our opinion, every argument in favor of a change; indeed, they are so obvious to every delegate and member who has to travel any distance during the worst winter month, and during the busiest professional season, that they need not be presented.

In conclusion, let us hope that there will be the usual good attendance, and that the usual harmony will pervade all the deliberations, whether for the government of the profession or for the advance of its scientific interests.

ARMY STAFF RANK.

As an evidence of the interest taken in the petition of the Army Medical Officers for increased rank and pay, we notice that the medical societies in this and other localities are appointing committees to draft appropriate resolutions endorsing the measure, and that they intend to leave no doubt in the minds of our legislators as to its imperative necessity. We can hardly imagine that any member of Congress can fail to see the justice of the demands; but the trouble may be, that it may appear to them so small a matter that action may be indefinitely deferred. There is no more effective manner of proving that the profession all over the country are determined to take a different view, than by the prompt passage of appropriate and telling resolutions. We have always thought that the profession could make itself a power if it only chooses to direct its concerted action in one direction; and the present seems a fitting opportunity to prove the truth of this

assertion. The bill will probably come up for discussion during the present month. Let each and every society take a part in the struggle, each and every physician take an early opportunity of bringing the matter to the attention of the Congressman of his district, that each and every member of our National Legislature may thoroughly understand the nature of the said bill and the reasons why the bill should pass. In another place we publish such of the resolutions as have been presented up to the time of our going to press.

Reviews and Notices of Books.

TRAITEMENT DE LA PLEURÉSIE PURULENTE CHEZ LES ENFANTS. (THE TREATMENT OF THE PURULENT PLEURISY OF CHILDREN.) By Le Docteur J. JOUGLA. Paris: F. Savy. 1873.

This little work of clinical and practical value has been prepared under the auspices of MM. Potain, Laboulère, and Bouchut, names which will no doubt add weight to it. It is divided into three chapters: the first being a general study of the affection; the second, of the therapeutic and operative measures of treatment, and the third, of the temperature in the affection. The clinical history, diagnosis, and prognosis are very clearly brought out by the author, and in the section devoted to therapeutics he gives the indications very fully. The clinical portion of the work is founded upon a number of cases which are recited in the body of the book. The author at the end appends the following conclusions:

1. The diagnosis of purulent pleurisy depends principally upon clinical thermometry.
 2. Surgical interference should be instituted much earlier in children than in adults, on account of the rapidity with which the thorax becomes deformed, and also on account of the morbid susceptibility of young subjects.
 3. The treatment should be to remove, by capillary aspiration, as much purulent liquid as possible, and to prevent the entrance of air.
 4. If the effusion does not reappear until after a long time, or in small quantity, the repetition of the puncture, with the same precautions, is interference under similar conditions as at first.
 5. If the pus is fetid, injections should be made with tincture of iodine or some other suitable application.
 6. If the purulent fluid is reproduced rapidly and abundantly, recourse should be had to drainage under water, to which may be added injections if the pus is fetid, and also in cases where it is thought that the secreting surfaces may be so modified as to cause them to secrete less.
 7. The injections may be made with the siphon apparatus of Potain.
 8. If grave symptoms continue or increase in spite of treatment, or if it is feared that the cause of them may be false membranes formed on the pleura, drainage must be resorted to.
 9. The strength of the patients must be sustained by therapeutics and appropriate hygienic measures.
- The injections used may be either that of Trousseau, tinct. iodine 50 parts, iodide of potassium 2 parts, water 100 parts, mixed with an equal quantity of tepid water, or diluted alcohol, or decoction of cinchona, or chloride of sodium, one part to fifty (Roper).

At the end of the work is a large plate of thermometric tracings.

LES TUMEURS DE L'OVARIE CONSIDÉRÉES DANS LEUR RAPPORTS AVEC L'OBSTÉTRIQUE. (OVARIAN TUMORS CONSIDERED IN THEIR BEARINGS UPON OBSTETRICS.) By Dr. JUSTIN TREILLE. Paris: J. B. Baillière et Fils. 1873.

In this work the author divides ovarian tumors into four classes:

1. Serous unilocular or multilocular cysts, with which are included hydatid cysts, which are exceedingly rare, Chalcot having published several examples. This class also accompanies often the following:

2. Dermoid cysts, in which sebaceous matter, fat, bones, teeth, and hairs, are found. For this reason they have been termed sebaceous cysts, adipose cysts, hairy cysts, pill-dental cysts. The genesis of these cysts has for a long time excited the sagacity of pathologists.

3. Malignant tumors of the ovary are not always isolated. Sometimes they are accompanied by serous or dermoid cysts, thus constituting complex tumors, cysto-sarcomas, cysto-carcinomas, etc.

4. Finally, ovarian tumors formed by extra-uterine pregnancy. This form was denied for a long time, but besides being borne out by physiology there are authentic cases (Keller: Thèse de Paris, 1871), in which the pregnancy took place in the ovary. After a very careful consideration of the whole subject, the author condenses his material into the following propositions:

1. A total and absolute degeneration of the *couche originée* is necessary in order that conception should be impossible, even if other portions of the generative apparatus preserve their integrity and exercise their function.

2. Cases of sterility are frequently met in women having ovarian tumors; in these cases it is necessary to seek the cause in the alteration of position and structure which these tumors produce upon the uterus, and more especially upon its neck.

3. The excessive indulgence in venereal pleasures, though they may have no influence in the production of these tumors, may at least provoke in them an inflammation of which the result is not always favorable. It is the beginning of this unfavorable state that reproduction exercises upon tumors of the ovary an influence, of which the dangers increase in proportion as the gravid uterus runs through its stages of evolution, attains its height of intensity during expulsion, and reacts also upon the childbed.

4. In order to convince observers of this dangerous influence, it is sufficient to enumerate the troubles observed during gestation, accouchement, and the puerperal lactation, namely, rupture, inflammation of the tumor, strangulation of the pedicle, abortion, uterine displacements, rupture of the uterus, a labor so complicated as to necessitate the whole series of obstetrical operations, even to embryotomy and Cæsarean section.

5. When the tumor forms an obstacle to the free passage of the child, we would suggest the following indications:

1. If possible, to push it back out of the true pelvis.
2. To draw off the fluid contents of the tumors, and to be very careful in opening solid tumors.

3. In case of a solid and non-movable tumor, to act as in a case of bony obstruction, to reduce the volume of the child by the usual means, always taking care not to wound the tumor, as that would expose the patient to fatal consequences.

4. If it is impossible to bring the child, mutilated,

into that portion of the pelvis left free by the tumor, practise gastrotomy; but decide at the beginning of the labor, in order to save the child and give the mother some chances of a cure.

6. If the enormous expansion of a serous cyst is a cause of worryment to a pregnant woman, recourse should be had to puncture as a palliative measure.

7. During the lying-in state a tumor may be punctured, of which the volume, its inflammation, or rupture, might compromise life.

8. The dangers which we have enumerated might induce us to recommend premature delivery, if abortion in the early months was not always a very serious matter.

Premature artificial delivery has given very deplorable results; however, it may be practised in the case of a solid tumor so adherent that it could be pushed back, and sufficiently small as to permit, without wounding it, the passage of the child.

9. Observations of ovariectomies performed during pregnancy authorize us to recommend them in the early days of gestation, when a very grave danger arising from the tumor menaces the life of the mother.

10. Medical treatment of ovarian tumors in pregnant women is useless and dangerous, and should be proscribed.

The subject is carefully studied, and is supported by a large amount of clinical knowledge, but a vagueness of expression mars its pages considerably.

DU TRAITEMENT DES POLYPES LARYNGIENS. (ON THE TREATMENT OF LARYNGEAL POLYPL.) By Dr. CHARLES LIVON.

The studies necessitated for the elaboration of this brochure were prosecuted by the author in the hospitals of Marseilles, chiefly under the direction of Dr. Nicholas Duranty. The author gives a quite complete history of the affection, considers its bibliography at some length, and presents very clearly the clinical features of a number of cases. He appends a résumé of his propositions at the end of the work. They are mainly as follows: Since the discovery of the laryngoscope, laryngeal polypi may be accurately diagnosed, and, consequently, rationally treated—a fact borne out by experience.

Three methods are at the command of the surgeon of relieving his patient of an affection not grave of itself, but which, by its development, may compromise his life by interference with respiration. These three methods are:

Their destruction by the natural passages.

By artificial openings.

By a combination of the two.

Each has been employed several times, and they can be supported by proofs.

The observations, although numerous, are not sufficiently so as to establish rules which should be followed. In the presence of the facts now at our command, the following statement may be made:

The method by the natural passages is the one which should be always tried, at least it has indications which render it most favorable to us; it is the most inoffensive, the least painful, and compromises in the least degree the patient's life. It sometimes requires more time, but has the least disadvantages.

The method by artificial passages is applicable when the first does not succeed or cannot be tolerated. Although presenting little gravity, it is always an operation which sometimes attacks the voice. It is perhaps more expeditious of performance and more precise than the former, but in practice it will be found

that many patients will prefer to remain several weeks under treatment than submit to an operation.

As this method involves several procedures, it is necessary to determine which to choose.

The answer cannot be given peremptorily, as the treatment is influenced by the diagnosis. In our experience two operations ought to fulfil all the indications. The first is the section of the thyroid cartilage, the second the incision of the thyro-hyoidian membrane. The first is applicable for cases in which polypi are found, from the ventricles of Morgagni as far as the commencement of the trachea. The second is applicable to cases of polypi of the upper portion of the larynx.

As regards the section of the crico-thyroid membrane, it should be exceptional, as it does not permit a sufficiently large opening. In complete laryngo-tracheotomy, unless under special indications, division of the cricoid cartilage should be avoided, as it is always useless and does not offer any advantages.

Finally, the combined method should be employed in cases where asphyxia has necessitated tracheotomy. As to tracheotomy itself, which is really a palliative treatment, it should only be performed in a case of violent dyspnea, where the seat and cause of the obstruction are unknown. In contrary cases recourse should be had immediately to laryngotomy, which will fulfil all the indications.

Ossification of the thyroid cartilage is not a contraindication to its section, for it only induces a little delay of cicatrization, and it is only exceptionally that its division produces perichondritis and necrosis, for in all the cases reported in this work in which this operation was performed, these accidents are not mentioned as occurring. The work is well studied out, and the author has taken great pains to familiarize himself with operative manipulation.

DU TRAITEMENT DE LA COQUELUCHE PAR L'HYDRATE DE CHLORAL ET PAR LE BROMURE DE POTASSIUM. (ON THE TREATMENT OF HOOPING-COUGH BY CHLORAL HYDRATE AND BROMIDE OF POTASSIUM). By DR. PIERRE ARMAND. Paris: Adrien Delahaye. 1873.

The author informs us that this work is the result of the observation of the treatment of twenty-three cases in the Charity Hospital of Lyons, in the service of Dr. Chatin. These cases are given in full, and besides there is a quite full bibliography. The conclusions of the author are as follows:

1. Hooping-cough is a spasmodic catarrhal affection, but the nervous symptoms are predominant when there is no complication. It is of specific nature, but has not a fixed and determined course. Art can interfere successfully in abridging its duration and rendering it more mild.

2. Bromide of potassium and hydrate of chloral have already been used with success by several therapeutists in hooping-cough. The results obtained have appeared superior to those given by most remedies.

3. The physiological properties of bromide of potassium and of hydrate of chloral permit a rational explanation of the mechanism of their action.

4. The observations which are reported confirm their efficacy in this disease, since we have almost always seen that under their influence the number and intensity of the fits of conghing are diminished, the vomitings cease, and that most frequently the duration of the disease appears shortened.

5. The bromide may be employed with advantage at the commencement of the convulsive period; the hydrate of chloral in the confirmed convulsive period.

6. The use of the bromide in moderate doses is not attended with any inconveniences.

7. The hydrate of chloral is almost always harmless. It should always be prudently given, especially in the commencement, in consequence of the intolerance to it observed in some subjects.

8. These two remedies, but especially the chloral, are contra-indicated in cases complicated with severe bronchitis or broncho-pneumonia.

ETUDE SUR LE CANCER PRIMITIVE DES VOIES BILIAIRES. (STUDY UPON PRIMITIVE CANCER OF THE BILIARY DUCTS). By Dr. F. VILLARD. Paris: A. Delahaye. 1872.

The author of this well-written little brochure informs us that it is mainly based upon the observation of a case in the service of Dr. Besnier, in the Hôpital Sainte Antoine, Paris, and besides this upon two cases belonging to M. Charcot. He has also collated other cases from various sources. He enters fully into the history, pathological anatomy, etiology, symptomatology, and clinical history of the affection, and at the end of his work gives the following résumé of its contents:

1. Primitive cancer of the biliary ducts, an affection relatively rare, may occur in four different forms: encephaloid, scirrhus, colloid, and villous. Under whatever form it may develop, the morbid process always begins in the submucous connective tissue, and it is only later on that it invades the mucous and muscular coats. Among the interesting anatomic-pathological peculiarities which may arise from cancerous degeneration, it is well to note the formation of calculi and the dilatation of the biliary ducts. Consecutive to this dilatation an inflammation often supervenes, and a supuration of the hepatic ducts, which may burst and give rise to interstitial hepatitis.

2. Cancer of the biliary ducts is ordinarily observed in old persons, and oftener in woman than in man. Heredity does not appear to have any influence in its etiology.

3. A pain in the right hypochondrium, assuming sometimes the character of hepatic colic, an ovoid, globular, sometimes nodulated tumor, situated at the spot where the gall-bladder usually is; icterus with its consequences, sometimes fever of an intermittent type; the symptoms of cancerous cachexia are the principal symptoms of cancer of the biliary ducts, an affection of which the diagnosis is always difficult, and of which the termination is always in death. The work is of its kind admirable. The conclusions are clearly and fairly drawn, and the clinical points of the cases admirably worked up; besides this, the diction is clear and simple.

A MANUAL OF MEDICAL JURISPRUDENCE. By ALFRED SWAINE TAYLOR, M.D., F.R.S., etc. Seventh Amer. ed. revised from author's last notes, and edited, with additional notes and references, by John J. Reese, M.D., Prof. Med. Jurisp. and Toxicology in the Univ. of Penn. Phila.: H. C. Lea. 1873. pp. 879.

THE PRINCIPLES AND PRACTICE OF MEDICAL JURISPRUDENCE. By ALFRED SWAINE TAYLOR, M.D., F.R.S., etc. Second Ed. In 2 vols., 8vo. Phil.: H. C. Lea. 1873.

Both of these works, by the same author, treat virtually of the same subject, and yet are distinctive enough in their characters to make one independent of the other. The Principles and Practice of Medical Jurisprudence, although much the larger work of the two, owes its inception and elaboration to its distinguished predecessor the Manual, which has run so triumphantly within the past few years through seven editions. This last edition of the Manual is probably the best of

all, as it contains more material, and is worked up to the latest views of the author as expressed in the last edition of the Principles. Dr. Reese, the editor of the Manual, has done everything to make his work acceptable to his medical countryman. Not only has he added nearly a hundred pages of valuable original matter in the shape of notes, etc., but has retained the additions, appropriately bracketed, of the two former editors, Dr. Hartshorne and Mr. Penrose. The notes of these gentlemen give a particular value to the edition, and especially those of Mr. Penrose, who has done so much to adapt it to the wants of the American bar. As its name implies, it is intended to present the science in abstract for the guidance of medical students and younger practitioners, in trivial cases, the details being disposed of in the larger work.

Speaking of the larger work as an edition, all we can say is, that it is abreast of the times and fully sustains the enviable reputation of the first edition. All the important medical cases are worked up to date, necessitating the addition of much new material, and much modification of older material. Some changes have been made which seemed to the author to be necessary to make the work even more acceptable. The subject of medical evidence has been much elaborated, and deserves the most careful and studious attention of every physician. In these times, when any medical gentleman is liable to be called upon for an opinion, it is more than ordinarily necessary that he should be prepared to give it, and have a knowledge and appreciation of the general principles upon which to act in such emergencies as will every now and again arise.

The remarks on the subject in question cover the whole ground, and leave nothing to be desired on the part of any one who wishes to acquaint himself with the requirements of his position as an expert, professional or accidental.

Other portions of the work have been enriched by many additions. The sections on wounds and cicatrices, especially the latter, are particularly well worked up. The section on poisoning contains the notice of some new toxic agents, their effects, and the methods for their detection. Large additions have also been made to the chapters on criminal abortion, life insurance, insanity, and infanticide. In fact every department of the science has received its due share of attention; all the important facts bearing upon the leading and representative medico-legal cases have been presented in a remarkably condensed and intelligible manner. The deductions from these cases are, as they should be, general in character, the author being content to leave elaboration of details of particular or special points to the reader, by the aid which is afforded by a reference to the cases themselves as reported in full in the different law reports of this and other countries. As a whole, the work is unequalled, and fully sustains the reputation which it has earned of being the standard authority upon the subject.

ESMARCH.—The method of arresting hemorrhage during operations, introduced by Prof. Esmarch, has been lately employed by Dr. Figaro, House-Surgeon at Bellevue Hospital, in a case of amputation of the thigh. Not a drop of blood was lost, and the tissues of the limb, when cut, presented a more blanched appearance than the cadaver. No unpleasant results have attended the case thus far. The saving of even a small quantity of blood is sometimes of great importance, and that is one of the advantages attending the method.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 26, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

FIBRINOUS CASTS OF BRONCHIAL TUBES.

DR. AUSTIN FLINT exhibited some casts of bronchial tubes which were expectorated by a medical gentleman in Canada, who wrote the following letter explaining the specimen :

ONTARIO, CA., Nov. 17th, 1875.

"DEAR SIR:—You will perhaps recollect that on the 21st of June last I called to consult you with regard to my lungs. You diagnosed slight tuberculosis in the apex of the right lung. You stated that you thought I could live it down, and said you regarded the slight attacks of bleeding beneficial rather than otherwise. You recommended me to use no medication except quinine as a tonic, and strongly urged every kind of *regimen* calculated to improve the general health. On my return home I had a slight bleeding, amounting to perhaps in all two ounces. I took quinine as you recommended, avoiding exposure in going out at nights, and soon recovered a good appetite and much better general health. I had no further bleedings from the lungs until the 20th of October, when, on returning home one evening after a long walk, which produced no fatigue whatever, I spat up about an ounce of fluid blood. I continued for six days to spit up from one to two ounces morning and evening, and on one occasion during the daytime, during which time my appetite was exceedingly good. Up to this time I had gained about ten pounds in weight, and thought my chances of recovery improving. After the six days' bleeding I began taking quinine again, and felt very well. On the 13th of the present month bleeding began again, more copiously than at any other former time, and continued so on the 14th at intervals of a few hours. On the night of the 14th I was attacked with a severe rigor, followed by heat, thirst, cold feet, and headaches; about two o'clock in the morning I began to get up membranous casts from the bronchi, 'a sample of which I have sent you by parcel-post accompanying this letter.' For about twenty-four hours I continued to expectorate these membranous bodies, and always accompanied by gushes of an ounce or two of blood; during the twenty-four hours I expectorated fully sixty ounces of blood, leaving me, of course, very weak, and I apprehend the casts are not all yet. I should perhaps mention here, that during all the summer I had a slight cough in the morning, with expectoration of a drachm or two of thickish mucopurulent matter and considerable thin frothy mucus; there was also during this time slight dullness over the apex of the right lung, with an occasional suberepitant rale about the upper part of the lung. Expansion on inspiration was somewhat restricted, and there were vague pains in the right shoulder. The evening I began to expectorate the casts I labored under severe febrile excitement, and the expulsion of each mass was always preceded by an aching pain in some part of the right lung; sometimes beneath the scapula, sometimes in the clavicular space, under the arm, and towards the last at the base of the lung. Yesterday and to-day the bleeding has ceased, with the exception of small clots, and I notice that the apex of the lung expands

much more freely and is far more resonant than prior to the expulsion of these membranes. This circumstance is also verified by a physician who has examined the lung on various occasions during the past two or three years. Now then, sir, you will perceive the difficulty I am in, finding this state of things to agree so closely with the description in your own valuable work on the chest, of pseudo-membranous bronchitis; the diagnostic remarks of Mr. Costa, and the two cases related by Watson, when both yourself and Prof. Alonzo Clark, on personal examination, agreed exactly that the affection was tuberculosis. Of course I fully appreciate the utter impossibility of knowing of their existence until expectorated, and the question so important to me now is, whether you believe these casts to coexist with tuberculosis. I may say, that on the most minute examination I cannot find any other matter than these fibrous casts and the blood. I should also add for your information, that about six years ago I had a pneumonia on the right side, lasting about six weeks, during which time the lower two-thirds of the lung was quite flat on percussion, and during this attack I had scarcely any expectoration, and certainly no nasty sputa whatever. I should judge, from the number of membranous casts I collected, that they penetrate into every bronchial tube in the right side, beginning about the first branches of the right bronchus; the first large piece that I got, considerably larger than any sent you, must have been from that point, or nearer the bifurcation of the trachea; the points that seem not to be cleaned out, and where there is still slight wheezing, are just near to the sternum, at the apex of the lung, and in the posterior and inferior part of the lower lobe. After these things were expectorated, the air was very irritating to the right lung, but now I can fill the lung very well without much irritation or coughing. The only thing that I need add is, that yesterday and to-day there is considerable febrile excitement, with headache and flushed face, thirst, and rather excited action of the heart. After your great kindness, and so carefully examining my chest in June last, I am sorry to give you the trouble of reverting to this matter again, but I should esteem it a very great favor if you would give me your opinion again after this new feature. Do you believe that all the symptoms proceeded from this fibrinous deposit, or do you think that is in any way connected with, or a part of, tuberculosis? I consulted Prof. A. Clark the same day I saw you, and, as before said, his opinion agreed precisely with your own. If it should come in your way, you can show him the specimen and refresh his memory as to the case. You are also at perfect liberty to make any clinical or other use of these rare things and peculiar symptoms, all of which can be verified, if necessary, by Dr. Bowlby, of this town. You will please excuse any incoherency or inaccuracy in this statement of the case, as I am at present too weak to do the matter justice. Again apologizing for troubling you, I beg to remain, my dear sir,

Yours truly,

"TO AUGUST FLINT, ESQ., M.D., New York."

Dr. FLINT remarked: The interesting question, I suppose, is, Whether these casts are coagulated fibrine, as the result of hemorrhage into the bronchial tubes, or whether they may be, as the writer hopes they are, exudations as the result of bronchitis? I could draw no other inference from the general history than that the former was the case. In substantiating this opinion he read the following result of microscopical examination by Dr. Janeway:

The microscopic examination of cast from bronchial tube shows: I. Fibrillary fibrine arranged in a network, with a predominating longitudinal direction. II. Red blood-globules without any color, some still retaining their shape; others variously deformed and shrunken. Some were in heaps, and so arranged as that it was difficult to decide on their true nature. III. A small amount of hematinoid in small flakes and crystals. IV. A few white blood-globules. V. A few pavement epithelial cells (probably from mouth). The examination leads me to believe these casts to be the result of the hemorrhage.

Dr. JANEWAY presented a specimen of cerebral embolism, without any heart-murmur coming from thrombosis of the heart. The patient was admitted into Bellevue Hospital the week before, in an unconscious state, with paralysis of one side of the face, right arm, and partial paralysis of right leg. On careful examination no cardiac lesions were discovered, and the diagnosis was undetermined. The patient lived but two days, and died comatose.

At the autopsy the left anterior two-thirds of the brain was softened. The middle cerebral artery was plugged up, for an inch beyond its bifurcation, with a reddish-gray clot, and the anterior cerebral was likewise plugged with a clot, which was situated just behind the anterior communicating artery. On examination for the cause of this clot the heart was examined, when a thrombus the size of a large pea was discovered, a piece of which, corresponding in size to that found in the arteries mentioned, was discovered. The origin of the thrombus was not known. The legs of the patient showed the existence of chronic eczema, leaving the presumption that her nutrition and strength were somewhat below par.

He referred in this connection to a similar case which had come under his observation, four years ago, at the Charity Hospital. In this case, however, there was no loss of consciousness.

The cases were interesting as proving the possibility of heart-thrombus existing without any cardiac symptoms being present.

Dr. BLAKE presented a tumor, which he had removed from the right mammary region of a boy aged ten years. The growth was first noticed at birth, and was about the size of a pigeon's egg; but for the past few months it had grown quite rapidly. It had all of the appearance and much of the feel of a lipoma, and appeared to be non-adherent to adjacent parts. At the operation, however, it was found to adhere below to the pectoral, and above to the skin. Instead of being a lipoma, and solid, it was discovered, on section, to be a cyst filled with blood and bloody serum, and was a striking example of the variety of tumor described by Paget as sanguinolent and resembling the interior of the auricle of the heart.

Dr. SELL exhibited some photographs. The first was an example of ossification of some of the muscles. The subject was dissected by Mr. Richard Bookay, in the Pathological Theatre of Dr. Steeven's Hospital, Dublin, in December, 1871. At the age of five years she was gored by a bull, and from that time she became unable to make proper use of her upper limbs, and other parts; she does not appear to have suffered pain at any time; she contracted a double pneumonia, of which she died in about two days. At the post-mortem I found no lesion of any of the viscera, except a uterine tumor and polypus. The vascular system was normal. I should state that both lungs were found in a state of intense congestion. The ossifications are seen in photographs, except two isolated bones, which were found in the muscles of the leg. One

of those I examined with the microscope, and found it true bone. I have subjoined a chemical analysis of it by Dr. A. Bell:

BONE FREED FROM FAT.

Organic matter.....	45.3
Phosphate of lime.....	45.47
Excess of lime existing as a carbonate and fluorine.....	7.78
Soluble salts of magnesia and fluorine.....	1.45
	100.00

The second photograph was of a case likewise dissected in Dr. Steeven's Medical School in the winter session of 1869. M. Murphy, a lunatic, aged 70 years, an extremely muscular man. At the post-mortem the only thing abnormal in this was a fracture of the first rib on the right side. The deltoid crest on the left humerus was elevated about one-fourth inch. The large rib-like bone seen in the photograph existed in the glutæus maximus. No inflammation either of the skin or muscle existed, or any other abnormal ossification in the muscles. This bone shows bone-cells, etc.

A third photograph was a representation of a man who had been tattooed over the whole surface of his body. The patient had exhibited himself in various medical centres of Europe, and was considered to be a curiosity in its way.

Dr. Mason referred to a case of his where the central portion of one side of the diaphragm was ossified.

Dr. FINNELL presented a specimen of necrosed bone, which he had removed, by operation, from the tibia, for the purpose of asking when was the proper time to perform such operations.

Dr. MASON remarked that he believed the rule was to remove the bone as soon as it was found to be loose.

The Society then went into Executive Session.

Correspondence.

TUNNELLED URETHRAL INSTRUMENTS.

A REPLY FROM PROF. W. H. VAN BUREN, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—May I tax your courtesy, Mr. Editor, to publish the following note in answer to "a second letter from Professor Gouley, M.D.," concerning "the invention of tunnelled urethral instruments," which appeared in a recent issue of your journal? The matter of my note must be somewhat personal in its bearing—not wholly scientific, and I ask this privilege with reluctance; but the base and odious charges of your correspondent, both directly and by implication, against me and my friends, cannot be allowed to pass unchallenged. I make this reply entirely in deference to those of your readers who may have no personal knowledge of your correspondent or myself. To those who know us I should consider any reply unnecessary.

Gouley became my assistant when I occupied the chair of Anatomy in the University in this city, nearly twenty years ago, as dissector; I had him afterwards appointed as my Demonstrator, and, still later, placed him in charge of my clinique on genito-urinary diseases. By degrees he became my assistant in private

surgical practice, and necessarily familiar with my views and ambitions in surgical matters. In return I tried to teach him, as far as lay in my power, and, as he got on, investigated and studied new subjects with him—as a senior in our profession does with his junior. I also did, from time to time, all I could for his personal advancement: secured his appointment as one of the surgeons at St. Vincent's Hospital; aided in getting him appointed as surgeon at the Bellevue Hospital; recommended him as Professor of Anatomy at the Bellevue Hospital Medical College; used my influence with the Surgeon-General to have him placed in charge of a general hospital during the war; advised the President of the Faculty of the University to retain him in charge of my clinique after my resignation; recommended him to my private patients; gave him surgical cases for operation; and, in short, befriended him in many ways.

Towards 1870 circumstances led me to gradually break off these intimate relations, and, about this date, I formed a new professional partnership.

I trust that this statement will justify the error of a cotemporary, who, apparently knowing our close professional association and the difference in our ages, assumed that your correspondent was a student in my office. In accordance with the "accuracy" which he arrogates to himself, he certainly was not. But what sort of accuracy is that which busies itself disputatiously with the technical meaning of a phrase, and at the same time is blindly ignoring notorious facts which destroy entirely its significance and applicability?

For some years previous to the war, both at Bellevue and at the New York Hospital, with large opportunities for gaining practical experience, I had been striving to perfect the details of the operation known as "the perineal section," in the hope of rendering it more easy of performance and more certain in result, and thus of extending the range of its application, which had been heretofore limited to desperate cases of advanced urethral obstruction. In other words, I was trying to convert the blind and uncertain "perineal section" of former days into the operation of "external perineal urethrotomy on a guide," as I afterwards called it. I found that the delicate grooved staff of Syme, on which this great surgeon proposed to cure old and resilient strictures by cutting them from the perineum, was, in less skilled hands, a dangerous instrument.

I also found that the delicate filiform bougies, when I first got them from Paris, enabled me to get into the bladder, with the potent aid of anaesthesia, in many cases of bad stricture otherwise impassable, and, adopting Syme's doctrine, but rejecting his instrument, I cut these cases successfully on the filiform bougie. Following Syme's operation as closely as possible, I introduced a full-sized grooved staff (with the groove open to its extremity), down to the perineal stricture, so that the beak of the staff represented the "shoulder" of Syme's instrument, whilst the filiform bougie occupying its groove, and projecting beyond its beak into the bladder, replaced (safely) the delicate grooved portion of his staff. It seemed to me that this mode of approaching an old and deep stricture by the knife, from without, was more safe and easy of general application than Syme's method of insinuating through it a fine-grooved steel rod, with a defective curve. I found that it was not always easy to carry the full-sized grooved staff down to the deep stricture, and at the same time to keep the filiform bougie in its groove: other strictures nearer the meatus were often in the way. To obviate this difficulty I bridged the groove

in the staff for its last three inches, and, threading its tubular extremity over the thread-like bougie, carried it somewhat more readily down to the stricture. I got this idea from Wakley's "railroad" instruments for stricture, which had been recently brought out from London. As this instrument did not work entirely well, I diminished the length of its bridge or tubular extremity to an inch and a half, and still later, in trying to adapt this device to the management of stricture complicated with false passages, I had the tunnelled portion diminished to less than the third of an inch, with its extremity made conical (like the metallic tip of Wakley's catheters).

I have these instruments in my possession, subject to the inspection of any who may desire to see them.

I may add, incidentally, that I had occupied myself as early as 1853 in the anatomical study of the curve of the fixed portion of the urethra; and, later, in the effort to secure the making of steel sounds adapted to this curve. These, with a slight degree of conicity towards the beak, and above Nos. 6 or 7 in size, I have employed for more than 15 years in the treatment of stricture by dilatation. I also satisfied myself, very early, that it was wrong to tie a catheter in the bladder after "perineal section," and adopted the practice, which the anæsthetic condition of the patient so greatly facilitates, of thoroughly dividing all the strictured points of the urethra during the operation, until it permitted the ready introduction of a conical steel sound of fullest size. This accomplished, I allowed the patient to void his urine at will through the perineal wound, tying no catheter in the urethra, and contenting myself with the careful introduction every day, or every second day, of a full-sized steel sound. I had, meanwhile, reviewed and tabulated all the recorded cases of perineal section which had occurred at the New York Hospital since its foundation, with the intention of publishing a monograph, containing the points of practice which I thought I had established; but the exigencies of the war, and the pressure of the new and responsible duties which it imposed upon me, cut short my design, and, in the end, broke down my health. Returning from Europe in 1865, I brought some new and fine filiform bougies of whalebone, and also a new stricture-dilator, which Mr., now Sir Henry, Thompson, had kindly had made for me, as better, in his opinion, than Mr. Holt's. Whilst showing these to Gouley, I said to him, "Now, if we can get a hole drilled in the beak of this dilator, so that it can be threaded on one of these whalebone bougies, we can perhaps run it down through the stricture more readily than on the ordinary 'gum' bougie, and thus in a case complicated with false passages, we can dilate or split, and thus gain command of the stricture," or words to this effect. He said he would see what the instrument-maker could do, and in a few days brought me a Thompson's dilator, with its beak perforated, and made to unscrew. I disapproved of the removable beak, as possibly dangerous, so he had another made nearly in the form now in use. Most certainly, at this date, there was no word breathed to me as to any "invention" on the part of Gouley. He had the instruments made for me, at my suggestion, as he had been in the habit of doing for me for years, for he had kindly taken the trouble off my hands of personal interviews with the cutlers (with occasional exceptions) for, I should say, ten years before this date. These instruments were charged to me, have been paid for by me, and are now in my possession. I have used them with some advantage, and will discuss their merits elsewhere.

These, Mr. Editor, are the facts which, at a later

date, I communicated to my friend, Dr. Bumstead, in answer to his inquiries. He used them as he saw fit. I had then no idea or design of establishing a claim to original invention; nor have I now. In suggesting the perforation of the beak of Thompson's dilator, I was simply conscious of a desire to carry out an idea with which I had been familiar for years, and for which the credit of originality, I think, goes back as far as old Desault's open catheter and whalebone conductor, two feet long, as adopted and improved by Phillips, and recommended by him in retention of urine from prostatic obstructions.* I should think the real invention—the "*procédé de Gouley*"—probably came later. I mean the invention of "*a method*," and not "*the principle*." (See RECORD, Dec. 15th, p. 625.) I did not hear of it from the inventor himself until after our business relations had ceased. When, in 1870, he addressed to me a formal demand to disavow all previous knowledge of "tunnelled instruments," it may well be conceived why I asked for an explanation. At the interview that followed I recalled to him the facts I have stated, saying, that it was impossible for me to ignore them even to oblige him, but that I would advance no claim to invalidate any invention of his, and advised him to follow kindly rather than war-like counsels. He expressed himself, as I thought, well disposed to follow my suggestion, saying, amongst other handsome things, that "I had been his master in urethral surgery," etc. But, alas! this must have been another "ingenuous expression of a generous impulse" (see RECORD, p. 626), for his "letters" have since shown evidence of a most truculent spirit.

Of the "book," and the note I wrote its author thanking him for it (which he prints), I am free to confess, Mr. Editor, that, at the time of writing, I had read but the "preface" and "contents," was very favorably impressed, and had it only in my mind to acknowledge a courtesy in a kindly manner. But I have since read enough of it to find that my old good feeling for its author led me into an error of expression; I recognize in it a good deal of my own teaching, but less acknowledgment of that teaching than I should have a right to expect from an "*accurate*" person, especially when that person had been the recipient of benefits at my hands. To this, however, I must submit. That particular lack of virtue which the Athenians punished as a crime is not included in our written code.

The name of Dr. Bumstead is also introduced by your correspondent, and treated with ignominy. I need not say that the slurs directed against him have no foundation in truth. The author of the best and most judicial work on his specialty in our language can afford to ignore insinuations which are as disingenuous and unjust as they are discourteous.

I trust, Mr. Editor, that I shall not again have occasion to ask you to insert in your columns any further controversial notes from me, and, so far as I am interested, the discussion must end here. Judging from the communications I have been receiving (which I shall not publish), I should infer that the sympathy your correspondent has tried to evoke has not fallen entirely to his share, and that there are some who believe that the aggressor in this matter is not

Yours truly,

WM. H. VAN BUREN.

104 MADISON AVENUE, Dec. 30th, 1873.

* I think any one who reads Phillips's article on the "*Introduction de la sonde sur un conducteur*," will agree in this opinion. (Vide Phillips's *Traité des maladies des voies urinaires*, Paris, 1860, p. 425.)

A REPLY FROM PROF. FREEMAN J. BUMSTEAD, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I should have replied to Dr. Gouley's first letter to the RECORD upon this subject, had I not felt that the matter lay entirely between him and Dr. Van Buren.

His second letter, which appeared in your issue of December 15th, indulges in personalities with regard to myself to which I have no desire or intention of replying; but his charges against me of unfairness as an author, demand that I should explain my position to the readers of the RECORD and the readers of my book.

In the autumn of 1869, I was one evening engaged in writing an article on Stricture of the Urethra for the *American Practitioner*, when Prof. Van Buren happened to call at my office, and, in the course of conversation, the subject of "tunnelled urethral instruments" being mentioned, he remarked: "That is my idea;" and, upon my further inquiry, he repeated that the invention was his.

I confess at that time I was not fully aware of the importance of the subject; it did not occur to me that for the purposes of catheterization, etc., tunnelling the end of an instrument was such an immense stride beyond using the whole of it for a tunnel, as Wakley, and before him Foulker and Hutton, had already done, and that urethral surgery had been revolutionized by this new modification; I did not foresee the amount of paper and ink which might in future be expended upon the discussion of the subject; and I was little aware that a professional reputation might be at stake upon what I regarded, at the time, as so trivial a matter.

Relying, therefore, upon Prof. Van Buren's statement to me, I attributed this device to him in the paper which I was writing; and in the next edition of my book, which appeared in October, 1870, I said, when speaking of some improvements in urethral instruments: "In one of these inventions, original, I believe, with that eminent surgeon, Prof. Wm. H. Van Buren, M.D., the extremity of urethral instruments is perforated, like a canula, for a short distance," etc.

Meanwhile I had not spoken again upon the subject to Dr. Van Buren, nor had I then, nor have I since then, received any communication from Dr. Gouley in claim of the invention.

I saw Dr. Van Buren, however, in December, 1870, when he mentioned to me that he had received the letter from Dr. Gouley, already published by the latter in the RECORD; and I find in a note still in my possession, written by Dr. Van Buren to myself upon other matters, and dated December 21, 1870, the following sentences at the close:

"With regard to the question of originality in the use of tunnelled instruments raised by Dr. Gouley, I sent for him, and, recalling certain of our former conversations, in which I had suggested similar modifications to those now claimed as original by him, *he seemed satisfied.*" I declined to answer his letter farther. I have an instrument or two I should like to show some day, if this question retains any interest beyond the moment.

"Sincerely yours,

"WM. H. VAN BUREN."

Whether it has been my duty at any time to communicate with Dr. Gouley, or his to communicate with

me, if he had any strictures to make upon my statements, is a question which your readers, Mr. Editor, will decide for themselves; and I feel assured that his charges against me of bad faith, etc., etc., will be received at their true value as affecting both their author and myself.

Respectfully yours,

F. J. BUMSTEAD.

32 W. 25TH ST., NEW YORK, DEC. 20, 1873.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 19, 1873, to January 3, 1874.

ABADIE, E. H., Surgeon.—Granted leave of absence for four months on Surgeon's Certificate of Disability. S. O. 1, A. G. O., January 2, 1874.

BAILY, E. J., Surgeon.—Granted leave of absence for three months. S. O. 249, A. G. O., December 18, 1873.

STYER, CHAS., Asst. Surgeon.—Leave of absence extended twenty days. S. O. 67, Division of the South, December 16, 1873.

New Instruments.

A NEW WIRE SPECULUM FOR EXAMINATION AND TREATMENT OF DISEASES OF VAGINAL WALLS.

By J. G. PINKHAM, M.D.,

LYNN, MASS.

THE accompanying wood-cut represents a new and simple form of wire speculum, which in my hands has proved serviceable in the examination and treatment

of the vaginal walls. It consists of a single piece of wire, bent into the form shown in the cut. It will be observed that there is no soldering about the instrument, the ends of the wire being secured by a sharp turn around that portion which connects the spring

and blades. Hence it is easily made, and of slight cost. The blade can be of any length and shape desired, and the spring of any degree of strength. The upper wires can be moved up or down at the outer end, with the result of widening or narrowing the blades.

Pressure upon the base of the blades with the thumb and forefinger closes them, so that the introduction is easy. The exposure of the vaginal walls on all sides is complete. In some cases it gives a good view of the cervix, but it is not intended to be used in operations upon the uterus. In working about the meatus urinarius it is often of great service, especially in the absence of an assistant. Its merits are simplicity and effectiveness. It is made by Codman & Shurtleff, of Boston.

NEW SCISSORS WITH DOUBLE POINTS.

WE present our readers with a sketch of a new and ingenious instrument devised by Geo. Tiemann & Co., of this city, which will be seen to possess many advan-

tages, and to admit of a wide range of adaptation. As will be seen, it is a long scissors, the blades of which are attached to their respective shafts by universal joints, allowing the said blades to be deflected and fixed at any required angle. As a single instrument it will be seen to be a combination of many, and will doubtless prove of great value to such as are called to operate upon the uterus and throat. The peculiar situations of tumors in these localities very often require a particular curve or angle for easy and effectual manipulation; and when such necessary conditions can be fulfilled at the moment of the operation, the advantages of the instrument as a whole are quite apparent.

A NEW ILLUMINATOR.

ANOTHER new instrument, devised by the same firm, and of value in operations upon deep cavities, is an illuminator, a sketch of which we present to our readers. The instrument is mainly constructed of brass, and is provided with a lamp for kerosene or oil, the wick admitting of an easy adjustment by means of a

side-screw. The handle can be folded against the chimney, so that the instrument can be packed in a small compass. The light passes through a convex lens, and can, by means of a sliding-cap, be focused at varying distances from two to five inches. It may prove useful in operations upon the ear, vagina, rectum, and throat, and may be of great service in operations at night, where a strong and reliable light may not always be obtainable.

Medical Items and News.

THE DEATH OF DR. W. C. ROBERTS.—At a meeting of the New York Academy of Medicine, held in the lecture-room of Saint Mark's Church, Dec. 12, 1873, a committee consisting of Drs. G. M. Smith, Oliver

White, and J. L. Vandervoort, presented the following preamble and resolutions, which were unanimously adopted:

Whereas, It has pleased an all-wise Providence to remove by death William C. Roberts, M.D., Vice-President of the New York Academy of Medicine, therefore,

Resolved, That the Fellows of the Academy are called upon to mourn the loss of an associate, loved for his social qualities, respected for his courtesy and rectitude, and honored for his erudition.

Resolved, That the Fellows will ever pleasantly recall the brilliancy of his wit, the readiness of his anecdotal illustrations, the richness of his poetical and classical learning, and the happy fluency of his extempore speech.

Resolved, That the numerous productions of his pen will not only be an enduring monument of his industry, but will also permanently perpetuate the clearness of his acumen, the force of his logic, and the ripeness of his scholarship.

Resolved, That the Fellows attend his funeral in a body, and that a copy of these resolutions be engrossed in the minutes of the Academy, be presented to the family, and be printed in the medical journals of this city.

AUSTIN FLINT, M.D., *President*.

W. T. WHITE, M.D., *Secretary*.

HOMOEOPATHY IN THE UNIVERSITY OF MICHIGAN.—The Circuit Court of Washtenau County, Mich. (in which the University is located), refused on the twenty-third of December to issue a writ of mandamus compelling the Regents to appoint two Professors of Homoeopathy, in accordance with the law passed by the State Legislature at its last session. This decision probably disposes of this perplexing question, inasmuch as the Supreme Court of the State had previously made a similar denial, and these two preliminary rulings would seem to foreshadow the decision when the question comes up for final adjudication on full argument.

DR. T. MATLOCK CHEESMAN has been appointed by Major-Gen. Shaler, of the First Division N. G., to be Division Surgeon, with the rank of Colonel.

THE DEATH OF DR. ALFRED UNDERHILL.—At a joint meeting of the Medical Society of the County of New York, the New York Academy of Medicine, and the Medical Library and Journal Association, held in the lecture-room of Trinity Chapel, Dec. 11, 1873, the following preamble and resolutions, presented by Dr. Joel Foster, were unanimously adopted:

Whereas, It has pleased our Heavenly Father in His all-wise Providence to remove by death our beloved brother, Dr. Alfred Underhill,

Resolved, That while we feel and lament the great loss sustained by the medical profession, the Christian Church, the institutions of charity and the families to whom his life was devoted, we humbly bow to the

Divine will in this affliction, and acknowledge the goodness that sustained him in his painful and fatal illness, and enabled him to complete his earthly career, as he had long lived among us, strengthened and consoled by religion, and constantly enjoying the love and tender regard of family and friends.

Resolved, That our sympathy and sincere condolence are hereby tendered to the family of the deceased. In behalf of the medical profession, we gratefully point to his unceasing benevolence and patient devotion to duty, having filled with honor the highest offices in our Societies.

Resolved, That a copy of these resolutions be transmitted to the family of the deceased, and to THE MEDICAL RECORD and *New York Journal of Medicine*.

ELLSWORTH ELLIOT, M.D., *Chairman*.

W. T. WHITE, M.D., *Secretary*.

ARMY STAFF RANK.—The following resolutions were passed by the New York Academy of Medicine:

Resolved, That the New York Academy of Medicine do hereby cordially unite with the American Medical Association in their memorial to Congress in support of a bill to increase the efficiency of the Medical Department of the Army of the United States, now before that honorable body. They consider it an act of justice that the members of so important a branch of the service, gentlemen of the highest professional attainments and excellence of character, and charged with such weighty and responsible duties, should hold the same relative rank and enjoy the same emoluments as members of the other staff corps of the Army.

That it be respectfully urged upon the members of Congress to use their influence in support of the bill in question.

That a copy of the above resolutions, duly authenticated, together with a copy of the memorial pamphlet, be furnished to each member of Congress from each district.

Resolved, That a copy of these proceedings be furnished for publication to the medical journals.

JOHN C. PETERS, M.D.

GURDON BECK, M.D.

FRANK H. HAMILTON, M.D.

DEATH OF DR. JONAS P. LOINES.—At a special meeting of the Medical Board of the Eastern Dispensary, held in the Dispensary rooms, December 17th, 1873, the following resolutions relative to the death of Dr. J. P. Loines were unanimously adopted:

Whereas, Our friend and associate, Dr. J. P. Loines, after a long and active career of usefulness in the cause of suffering humanity, has been suddenly removed from our midst by death, to our great and heartfelt sorrow; therefore, be it

Resolved, That in this dispensation of the Divine will we feel most keenly the stroke which has deprived us of the counsel, companionship, and assistance of one whose many excellent qualities of mind and heart had endeared him to each and every member of the staff of this institution.

Resolved, That in his death the Eastern Dispensary is deprived of the valuable services of one who for more than twenty years directed its internal management, and to whose prudence, fidelity, and skill its success and reputation are largely due, while his uniform courtesy and consideration of the feelings and rights of all who were associated with him enabled him to preserve unbroken harmony during the entire period of his administration.

Resolved, That the medical profession generally recognizes with gratitude his services as a scientific investigator, and the benefits which have accrued to

humanity from his achievements in the specialty to which for many years his attention was chiefly directed.

Resolved, That the poor of this Dispensary district lose in him a kind and faithful friend, one whose ear was ever open to their complaints, and whose sympathy and efforts in their behalf were spontaneous and unfeigned. His kindly face will be missed by them with unfeigned sorrow.

Resolved, That the house-staff of this Dispensary meet in this place at 11 A.M. to-morrow, the 18th inst., and proceed thence to his residence in Mount Vernon, to pay the last tribute of respect to his memory.

Resolved, That a copy of these resolutions be presented to his family, and that they be published in THE MEDICAL RECORD and the *New York Journal of Medicine*.

ROYAL B. PRESCOTT, M.D.

EDWARD FRANKEL, M.D.

H. LE BARON HARTT, M.D.

BELLEVUE HOSPITAL, NEW YORK.—Dr. W. H. Polk has been appointed one of the Visiting Physicians, *vice* Dr. B. W. McCready, resigned.

DR. E. PEGNET read a paper before the Medico-Legal Society, December 26, on the Medical Jurisprudence of the Stokes case, for the purpose of proving that wounds of the intestine are not so fatal as has been generally supposed; also that the cause of the death of Fisk was due directly to poisoning. The paper was discussed by Drs. Sayre, McCready, and others.

DISTRICT MEDICAL SOCIETY, COUNTY OF HUDSON, NEW JERSEY.—We have received a second list of officers of this Society, and as each list is claimed to be the correct one, and as we have no means of judging the particular merits of the case, we present them both. As the case now stands, it appears to be at variance with the axiom that two bodies cannot occupy the same place at the same time, and have the same name. The second list of officers for this year, elected December 2, 1873, is as follows: President, A. A. Lutkins, M.D.; Vice-President, B. D. Carpenter, M.D.; Secretary, H. Mitchell, M.D.; Treasurer, B. A. Andrews, M.D.; Reporter, E. W. Beck, M.D. Delegates to the State Medical Society, Drs. Vondy, Pendergrast, Cornelison, Hunt, Forman, Mitchell, Morris, Buffet, and Carpenter. Alternately, Lutkins, Andrew, Bird, Geisler, Burdett, Hardenburgh, Case, Van Houten, and Reeve.

THE CAUSE OF SIMILARITY IN TWINS.—Dr. J. F. Bird, of Philadelphia, writes:

It has long been my purpose to call the attention of physiologists and medical practitioners to the consideration of the probable causes of the fac-simile representation of twins. It is a question of considerable interest that twins should so frequently be so much alike that even their parents can scarcely know the one from the other, whilst other persons cannot at all determine which is "*Minnie*" and which is "*Bessie*." In my experience, and that extends to a number of well-marked cases during a period of over thirty years, I have invariably found that when twins are contained in the same sac, and sustained by the same placenta, they have always had a slavish resemblance to each other; whilst those contained in different sacs, and sustained by different placenta, are as unlike as children born of the same parents at different periods, however remote. This hypothesis is sustained, not only by actual and positive and repeated observation, but by inquiries made of other observers. In one family there are two cases of twins. The first pair were contained in

the same sac of waters, and are exactly alike; the other pair were delivered from different sacs, and are no more alike than are the other children. I delivered a case also of triplets. Each child was in a separate sac, and neither resembled the other particularly. Let these observations go to the curious or speculative members of the profession for what they are worth. I am satisfied with the theory, and believe that close observation will establish it beyond contradiction.

A FREAK OF NATURE.—Recently there was exhibited in Paris a Russian peasant and his son who had upon their heads and upper parts of their bodies a most remarkable growth of hair. The father, Andrian Jettichjew, aged fifty-five, was born near Kostrema, in Russia. His whole face, nose, forehead, cheeks, and ears are covered with long brown hair, which extends also down his back for some distance. The skin beneath the hair is apparently healthy, and no nevroid discoloration is to be seen even where the hair has been cut in order to enable the man to see. The French description likens his appearance to a "King's-Charles" (*sic*), but the resemblance is really more to a skye terrier.

The son, Fedor, is only three years old, and the hair is so much lighter in color, and less thick, that the skin is much more perceptible. A remarkable feature in both father and son is their nearly edentulous condition. The father is said to have had no teeth up to the age of seventeen, and then to have had four teeth only in the lower and one in the upper jaw, and his gums give no evidence of there being germs of other teeth within them. In commenting on these cases *The Lancet* says: "In a small work on the human hair, published in 1869, Dr. Herman Biegel has collected a number of cases of somewhat similar growth, the most remarkable occurring in a family in Burmah, three generations of which have developed a growth of hair on the face much resembling that of the Russians now being exhibited. Those individuals in Burmah had also the peculiarity of being nearly edentulous, one of them, a male, aged thirty, having only four incisors in the upper jaw; and another, a female, having the same absence of all back teeth, though her female child of five years is said to have a complete first set of teeth.

"The statement that a race of hairy men existed in Japan, has been supported by Mr. Martin Wood, who read a paper before the Ethnological Society of London, in 1865, on 'The Hairy Men of Yesso,' but denied in the 'Memoirs of the Anthropological Society of London,' by Mr. Bernard Davis, who shows that the hairiness of the bulk of the race in question is in no way exceptional. Virchow, also, in a lecture on this subject, states positively that neither in respect of the arrangement of the hair nor in regard to the teeth have these Ainos of Japan any analogy with the Russian or Burmese hairy men.

"Mr. Darwin, in his work on 'Animals and Plants under Domestication,' has not failed to notice the relations between the abnormal growth of the hair and the teeth, and is of opinion that these cases forcibly call to mind the fact that two orders of mammals—the edentata and cetacea—which are the most abnormal in their dermal covering, are likewise the most abnormal, either by deficiency or redundancy of teeth."

MODERN PRACTICE OF MEDICINE.—The London *Lancet* is responsible for the following witty anecdote of Dr. Robert Barnes, which may have more than a grain of truth in it: "I have recently been honored by a visit from a lady of typical modern intelligence, who consulted me about a fibroid tumor of the uterus; and

lest I should stray beyond my business, she was careful to tell me that Dr. Brown-Séquard had charge of her nervous system, that Dr. Williams attended to her lungs, that her abdominal organs were entrusted to Sir William Gull, that Mr. Spencer Wells looked after her rectum, and that Dr. Walshe had her heart. If some adventurous doctor should determine to start a new specialty, and open an institution for the treatment of diseases of the umbilicus—the only region which, as my colleague, Mr. Simon, says is unappropriated—I think I can promise him more than one patient."

RELATION BETWEEN WARTS AND DIFFERENT FORMS OF CANCER.—At the late meeting of the British Medical Association, Dr. S. M. Bradley read a paper in which he attempted to establish the essential oneness in origin of all morbid growths characterized by the abnormal development of epithelial elements, such, *e.g.*, as scirrhous, epithelium, epulis, and common warts. The author stated that the simplest of these tumors may evolve the more complex by the agency of external forces, such as irritation, pressure, etc. (the influence of heredity is probably always great in determining the exact nature of the morbid product); and that the power and rate of infiltration and invasion of the general system is due to simple laws, such as the size and shape of the cells, their degree of moisture, and the nature of the surrounding tissues. He maintained that, as electricity, by coagulating the albumen of a part, establishes a barrier to the onward march of the cell-elements, it should therefore be employed in all cases of infiltrating tumors when it is decided to eradicate the growth.—*British Med. Jour.*

THE NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.—The purpose of this Society is the study of the Anatomy, Physiology, Pathology, and Therapeutics of the Nervous System, and of Electricity in its relations to Physics, Physiology, and Therapeutics.

The following are the officers: *President*, Meredith Clymer, M.D.; *Vice-President*, Austin Flint, M.D.; *Recording Secretary*, Alfred L. Carroll, M.D.; *Corresponding Secretary*, John J. Mason, M.D.; *Executive Council*, Austin Flint, M.D., John C. Dalton, M.D., D. B. St. John Roosa, M.D., George M. Beard, M.D., Edward T. Loring, M.D., the President and Recording Secretaries, *ex-officio*.

The following are the Standing Committees:—*Anatomy and Histology of the Nervous System*, I. W. S. Arnold, M.D., Edward T. Janeway, M.D., Edward C. Seguin, M.D.; *Physiology and Pathology of the Nervous System*, John C. Dalton, M.D., D. B. St. John Roosa, M.D., Edward G. Loring, Jr., M.D.; *Psychology*, Meredith Clymer, M.D., Ralph L. Parsons, M.D., John O'Dea, M.D.; *Electro-Physics and Electro-Physiology*, John J. Mason, M.D., Alfred L. Carroll, M.D., Wm. R. Fisher, M.D.; *Electro-Therapeutics*, George M. Beard, M.D., John Byrne, M.D., A. D. Rockwell, M.D.

MEDICAL SCHOOLS AND GRADUATES.—There are in the United States, according to Dr. Toner, 101 medical teaching bodies, classified as follows: Regular medicine, 77, of which 16 teach pharmacy; 8 Homeopathic, 8 Dental, 6 Eclectic, and 2 Botanic.

The annual accession to the ranks of the medical profession through American colleges is, Doctors of medicine, 1,698; *Ad eundem* degrees, 79; Honorary, 16; and 5,776 matriculants attending college. He says, if the returns were complete from all colleges, it would probably reach 2,000 graduates, and perhaps 6,500 in attendance on lectures.

The whole number of the medical profession of the United States numbers 62,383.

Medical Department of Life Insurance.

AN INQUIRY INTO THE CAUSES OF 1,000 DEATHS,

BEING THE MORTALITY EXPERIENCE OF A LIFE INSURANCE COMPANY IN THE CITY OF NEW YORK.

By ALBERT H. BUCK, M.D.,

INSTRUCTOR IN OTOTOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

GENTLEMEN: *—At the request of your President I have instituted a careful inquiry into the death-record of this company, from its incorporation in 1850 to the present time—Dec. 27th, 1873. Such an inquiry, it was believed, would, on the one hand, throw light on at least some of the errors of the past, and so enable us to avoid them in the future, while, on the other, it would more clearly define the rules regarding health, personal habits, and family history, in accordance with which a financial success in assuring lives had already been attained. Many of our agents, too, were disposed to consider the rulings of the home office unnecessarily severe, and it therefore seemed very desirable, if possible, to show in the past experience of the company a justification for the course followed.

As a preliminary step to such a study, it was found necessary to gather together into a single volume, in systematic order, all the facts contained in the application, the medical examiner's report, and the "proofs of death" of those who had died during this period. This part of the work has been done in a very satisfactory manner by Mr. J. A. Marsh, of this city, and is submitted herewith for your inspection. The number of deaths involved in this inquiry is one thousand. The causes by which they were encompassed are set forth in the following table:

TABLE I.

	No. of Cases.
Abscess (of arm, parotid gland, and perineum)	3
Anæmia	2
Aneurism	4
Apoplexy	53
Assassination	4
Asthma	2
Bladder, inflammation of	3
Brain, acute disease of	36
Brain, chronic disease of	32
Bronchitis	7
Bowels, inflammation of	24
Calculus (biliary and cystic)	2
Cancer	22
Casualties (war, shipwreck, poison, and drowning)	54
Cerebro-spinal meningitis	7
Cholera, Asiatic	17
Cholera morbus	9
Consumption	268
Delirium tremens	10
Diabetes	7
Diarrhoea	9
Diphtheria	5
Dropsy	20
Dysentery	27

Epilepsy	2
Erysipelas	10
Exhaustion, from undue mental labor	1
Fever, continuous	60
Fever, intermittent and remittent	8
Fever, congestive	10
Fever, yellow	1
Gastritis	9
Heart, diseases of	49
Hemorrhage, internal, from strain	2
Hernia, strangulated	4
Hydrothorax	2
Intemperance (form of disease not stated)	6
Kidneys, chronic disease of	25
Lead disease	1
Liver, abscess of	4
Liver, cirrhosis of	5
Liver, cancer of	2
Liver, diseases of (forms not stated)	27
Lungs, abscess of, from embolism	1
Malignant pustule	2
Parturition	2
Peritonitis	4
Pleurisy	2
Pneumonia	81
Puerperal fever	1
Purpura hemorrhagica	1
Rheumatism, acute articular	7
Scarlatina	1
Small-pox	9
Stomach, ulcer of, with hemorrhage	3
Suicide	19
Stroke	2
Unknown (found dead, etc.)	10
	1,000

It will thus be seen that the most fatal element in our list of losses is consumption, which alone has been productive of nearly 27 per cent. of the deaths. The zymotic diseases—intermittent, remittent, scarlet, typhoid, and yellow fevers, small-pox, diphtheria, erysipelas, cerebro-spinal meningitis, cholera, dysentery, and diarrhoea—constitute the second largest group, including 198 cases, or nearly 20 per cent.

Next in order come the various diseases of the brain, such as apoplexy, congestion, inflammation, and softening of the brain, acute mania, epilepsy, and sunstroke. This group numbers 126 cases, or nearly 13 per cent. of the entire mortality. If we add to it the cases of suicide and delirium tremens, the group will number 155 cases, or over 15 per cent.

The acute diseases of the lungs—pneumonia, bronchitis, and pleurisy—constitute the fourth largest group, containing 90 cases, or 9 per cent. Finally, the diseases of the heart and larger blood-vessels comprise 53 cases, or 5 per cent.

Before entering into the particulars of these five groups, allow me to lay before you some statistics collected in the course of the present inquiry. It was found, for instance, that out of the thousand individ-

* This article was originally written as a report to the directors of the company.]

uals whose policies had matured by death, the heights and weights of 742 had been recorded by the medical examiner. As this number did not appear to me to constitute a sufficiently large basis upon which to found a table, I collected from the volumes of the medical examiner's reports the heights and weights of 897 other individuals (all males), thus making a total of 1639 individuals whose average age was nearly 37 years. The table of average heights and weights now in use among all life-companies in the United States is, I believe, a modification of Dr. Hutchinson's table, based upon 2,650 English lives.* The correctness of the modified table for American purposes is fully confirmed by the results of the present investigation, as set forth in the accompanying table:

TABLE II.—RELATIONS OF HEIGHT TO WEIGHT.

(Based upon 1,639 American lives.)

HEIGHT.	No. of Indiv. Involved.	Aggregate Weight. lbs.	Average Weight. lbs.	Average Weight (Hutchinson), lbs.	Average Weight (Amer. Standard), lbs.
4 ft. 9 in.	1	121	—	—	—
4 ft. 10 in.	—	—	—	—	—
4 ft. 11 in.	2	235	117	—	—

6 ft. 1 in.	20	3462	173	—	—
6 ft. 2 in.	9	1508	167	—	—
6 ft. 3 in.	3	630	210	—	—

GROUP I.

Diseases of the Heart and larger Blood-vessels.

In stating that there were but 53 cases in this group, I am confident that the number falls short of rather than exceeds the truth. Of the 2 cases of asthma, 2 cases of hydrothorax, 20 cases of dropsy, 25 cases of chronic disease of the kidneys, and 27 cases of disease of the liver, it is highly probable that quite a number were secondary to disease of the heart. The facts stated in the death certificates are not, however, sufficiently explicit for me to venture upon any more accurate diagnoses than those given in Table I.

The average age at death of the entire group is 49 years, distributed among the different periods of life, as indicated in Table III.

It will thus be seen that this form of disease is preeminently one of mature age, 56 per cent. of the deaths having occurred during or after the 50th year of life, and nearly 80 per cent. after the 40th. Another feature

* Dr. Hutchinson's table, based upon 2,650 men, is given in the Assurance Magazine (vol. 11, London, 1850). It is as follows:—

HEIGHT.	WEIGHT.
Ft. in.	Lbs.
5 1	120
5 2	126
5 3	133
5 4	139
5 5	142
5 6	145
5 7	148
5 8	155
5 9	162
5 10	169
5 11	174
6 0	178

of some practical importance is the fact that out of the 49 cases (excluding the 4 cases of aneurism), 15 gave a previous history of "rheumatism." None of these cases made any complaint of palpitation of the heart, shortness of breath, or any other suspicious symptom, at the time they were insured, and it is to be presumed that no physical signs were at that time discoverable which might have thrown light upon the subsequent cause of death. Hence, the only indication of the disease of which they were eventually to die lay in the circumstance of their having had "rheumatism." The fact, then, that 30 per cent. of all our losses through disease of the heart were known, at the time of issuing the policies, to have had rheumatism, would suggest the propriety of making an inquiry into the history of our rheumatic risks, similar to that which has been made in the case of those having a consumptive element in their family histories. (See farther on.) This investigation, however, must be reserved till some future time.

The ages at death of the four cases of aneurism average 50 years.

GROUP II.

Acute Diseases of the Lungs.

There is very little to say concerning the diseases of this group, except that they carry off some of our healthiest risks in the very prime of life. I know of no way of guarding against loss from this source, except, perhaps, by the exercise of caution in accepting persons whose occupation exposes them to sudden and great changes in temperature. Tables IV. and V. will show the seasons of the year when the disease is most prevalent, and the ages at which it is most likely to occur.

GROUP III.

Diseases of the Brain and Nervous System. Delirium Tremens and Suicide.

There are several questions of interest connected with the study of this group of diseases, but unfortunately the number of cases which it comprises is comparatively small, and the details of the individual histories are in many instances incomplete. Nevertheless the results are suggestive of certain inquiries that might profitably be made, were the material at one's command larger.

The relative frequency of these different diseases, and their distribution among the different years of the past, are set forth in Table VI.

Leaving out the cases of suicide, and separating the ages into periods of 5 years each, I find the apoplexies, congestions, softenings, etc., of the brain to have been distributed in the manner seen in Table VII.

The height and the weight were recorded in 116 out of the 156 cases. They are noticed in Table VIII.

As to the question of whether the disease was or was not in some instances hereditary, I would reply that in 10 cases the father was known to the company, at the time the policy was issued, to have died of apoplexy or softening of the brain, by suicide or by intemperance; that in 4 other cases the mother was known to have died of suspected brain-trouble; that in 4 others still, a parent, together with a brother or sister, were known to have died from the same causes; while finally, in 6 other cases one or more brothers or sisters were known to have been victims of brain-trouble. Thus it is possible that in a little over 15 per cent. of all these cases there was an hereditary taint predisposing the applicants to the disease of which they eventually died.

In 18, or a little over 11 per cent. of the cases, the family history was tainted with consumption. In 22, or 14 per cent. of the cases, the applicants had been at some previous time afflicted with "rheumatism."

The suicides are grouped in the foregoing manner according to their ages and methods of destroying life. (Tables IX. and X.)

GROUP IV.

Zymotic diseases: Typhoid fever, scarlet fever, yellow fever, intermittent and remittent fevers, cerebro-spinal meningitis, cholera, erysipelas, puerperal fever, diphtheria, small-pox, diarrhoea, and dysentery.

The recent epidemic of yellow fever in some of the South-western cities has been seriously felt by some of our neighbors, but as our own company has never issued policies on persons residing in the Southern States, except in isolated cases, it is not surprising that there should have been but a single death from that disease. The epidemic referred to, however, would probably not have proved so fatal to the better classes, had not the cities in which the disease prevailed been in such a deplorable sanitary condition. In the future it would perhaps be to the company's interest to note the sanitary condition of the towns and cities in which their policy-holders live, for the purpose of bringing influence to bear in favor of sanitary reform where such seems to be needed.

In regard to the continuous fevers, such as typhus and typhoid, a glance at Table No. XI. will show that

among our policy-holders no period of life has been specially liable to these diseases.

The only provision that can be made by the company to avoid an excessive mortality from this source is by not issuing policies, at least on the life plan, to men whose pecuniary circumstances compel them to live in the crowded tenement houses of our large cities.

GROUP V.

Consumption.

Our "proofs of death" are not sufficiently accurate to enable me to make a distinction between tubercular disease of the lungs and chronic bronchitis,—a form of disease so nearly like the tubercular variety in all its outward manifestations that I scarcely believe it will ever be possible in insurance statistics to call it by any other name than consumption. For practical purposes, however, it is not necessary to make such a distinction.

Consumption has at all times in the history of the company been the cause of a large percentage of its losses, no less than 263 or nearly 27 per cent. of the entire number of deaths having been due to this disease. The yearly losses from this source are seen in Table XII.

The first thing here that attracts our attention is the fact that while the mortality from consumption in the country at large is only 15 per cent. of the entire mortality, in the community of policy-holders—all se-

lected lives—it is nearly twice as great. It is easy to say that here is *prima facie* evidence of carelessness or incompetency on the part of the company's medical examiners, but it is a very difficult matter, if not altogether impossible, to satisfy the mind of the truth of this. I find, for instance, that out of the 268 deaths by consumption, 153 were originally examined and recommended for insurance by physicians of this city: 124 by Dr. James W. G. Clements, for nearly 20 years the medical director of the company, and 29 by Drs. Edward Fields, Wm. Macneven, J. W. Scott, George P. Cammann, John T. Metcalfe, Minturn Post, S. Conant Foster, and Charles D. Smith.* The 29 deaths that occurred among those examined by the eight gentlemen last mentioned, represent, in proportion to the total number of examinations made by them, a greater mortality from consumption than do the 124 originally recommended by Dr. Clements; and yet some of these men are—or were during their lifetimes—widely known as experts in physical diagnosis. I mention these points in order to show that the excessive mortality from consumption—at least so far as the New York risks are concerned—has occurred not through incompetency or carelessness on the part of the examiners, but rather in spite of the carefulness and skill which we have every reason to believe these men exercised.

As to the remaining 115 deaths from consumption, I am unable to arrive at any special conclusions why here, too, the mortality should have been excessive. I would call attention, though, to the fact that this mortality, in proportion to the total number of examinations made, is decidedly heavier than that which has occurred in this city and vicinity.

Before theorizing any further on this question, let us glance at some of the facts that may be gathered from a closer study of these 268 deaths. In the first place, we find that the average age at which they insured

their lives is 34 years, whereas the average age at which the remaining 732 became insured is 38½ years. The average age at death of the 268 is 39 years, while among the other 732 it is 44 years. In 76 cases (29 per cent.) there seems to have been a consumptive taint in the family. These cases are classified in the following table:

TABLE XIII.—CONSUMPTION.

It is a fact well known to the officers of insurance companies that the terms "childbirth," "change of life," "exposure," "grief," "fever," "inflammation of the lungs," and "general debility," used by the applicant to designate the cause of death of some member of the family, are in many instances synonymous with consumption. This is particularly true of the applications for insurance that come from agents in the country. Physicians who make but half-a-dozen examinations in a year are slow to learn the importance

* The writer at first doubted the propriety of mentioning names, but finally concluded that a record of a service so successful (as will be seen farther on) and also so creditable to the gentlemen in question, deserved to be made public.

* The causes of death, as stated, being "childbirth," "change of life," "fever," etc.

of a thoroughly sifted family history. I believe it is no exaggeration to say that about half of these cases would prove, upon careful inquiry, to have been genuine cases of consumption. With this in view I have constructed Table XIV., which shows that in an additional 24 per cent. of the deaths there was a doubtful family record.

It will, therefore, not be far from the truth to say that in about 40 per cent. of our consumptive losses the taint in the family history played an important part in determining the eventual cause of death. Further on I shall revert to this question and follow it out more closely.

The ages at which these 268 consumptives died are arranged in periods of five years each, as seen in Table XV.

From this table it will be seen that 60 per cent. of the deaths occurred between the ages of 30 and 45, or 73 per cent. between the ages of 30 and 50.

Our only way of judging of the physical condition of the 268 at the time they were insured is by ascertaining their average heights and weights at that time. On investigation, however, I find that the heights and weights, as ascertained at the time the policies were issued, have been recorded in only 209 instances. In these cases the average weights for the different heights are as seen in Table XVI.

As it is not likely that the weights of the remaining 59 cases would materially disturb the averages here given, I believe we can safely assume that these results represent correctly the average heights and weights of the entire group. Here, then, we find a second important general characteristic of these consumptive cases—a tendency to leanness, especially noticeable among the tall individuals of the group. This diminution in weight is even more marked than is the increase among the group of diseases of the brain and nervous system. Until we shall have reversed the investigation and ascertained what has been the mortality among all, or at least a large number, of our lean risks, it would not be safe to lay down any general rule regarding them. It is evident, though, that this class of risks must be accepted with caution.

An investigation into the physical histories of the group prior to insurance reveals only two points of interest: 7 per cent. of the number had been more or less subject to "rheumatism," and 5 per cent. had previously had "spitting of blood."

So far then as we have gone in this inquiry, the results obtained would seem to indicate the necessity for separate inquiries in regard to the mortality among—

1. Those who have had "spitting of blood," and those who have had a consumptive taint in their family histories;

2. Those who have been over or under the standard weight; and

3. Those who have had "rheumatism."

The last two of these inquiries will have to be postponed till some future time.

(To be continued.)

MORAL HAZARD IN LIFE INSURANCE.

THE heavy losses to which life-insurance companies are annually subjected from suicide, intemperance, and general recklessness of life, suggest the idea that far too little importance is ordinarily attached by the parties in interest to the moral hazard of the risks they assume.

The following extract from a forthcoming revised edition of "Instructions to Medical Examiners," will serve to show what is here referred to: "In addition to a sound physique, and an unexceptionable family record, medical examiners should also inquire into, and duly appreciate, the moral hazard attending any case which may present itself. Thus, for example, if the occupation, mode of life, social position, financial condition, domestic relations, or any other circumstance connected with the applicant's history be such as to render him indifferent to or reckless of life the fact should always be fully and clearly set forth, as having a most important bearing in determining the character of the risk. No one can be regarded as safely insurable if the desire for life, or the motives for living, have in any wise or to any extent been removed, and considerations of delicacy should not prevent the medical examiner from mentioning such facts when he has reason to suspect their existence."

This subject, which is one of importance, should commend itself to all persons interested in the success of legitimate life insurance, and caution and attention just here might be the means of preventing many an unnecessary loss which would otherwise arise. It is not proposed to pursue this subject further at this time than to remark, that the fact of men of limited means seeking to effect insurance on their lives to an amount far beyond their ability to carry, should of itself excite suspicion, and lead to an inquiry whether the object be not really to speculate on these beneficent institutions, rather than for legitimate purposes. It is

unfortunately true that men of lax moral principles, whose impaired fortunes may have rendered them reckless as to life, will sometimes prefer to provide for their dependent families by the proceeds of a life policy, rather than by trusting to the uncertain chances of attempting to retrieve their desperate fortunes from the proceeds of honest industry. Such persons too often swell the list of unfortunate suicides, and by preventing their fraudulent designs, we may not only protect life-insurance companies, but at the same time interpose a barrier against the horrible crime of self-destruction.

A MEDICAL DIRECTOR.

St. Louis, Nov. 26, 1873.

ON THE RELATIVE INFLUENCE OF CITY AND COUNTRY LIFE ON LONGEVITY.

(EXTRACTS FROM A PAPER READ BY JOHN STOCKTON-HOUGH, M.D.,
BEFORE THE PHILADELPHIA SOCIAL SCIENCE ASSOCIATION, 1873.)

In our theme to-night we have to do with the ill effects on health, mortality, and longevity, arising from prolonged or continuous life in cities. And these effects can best be shown and appreciated by comparison with the much more favorable results of life in the country.

On these several conditions hang the fates of principalities and powers. Well and truly has the Roman poet said: "*Pericula mille sæva urbis*"—a thousand perils beset the great city,—and these words have as much weight and meaning to-day as they had centuries ago.

On the other hand, the unsparing praises of life in the country, with its attendant happiness, healthiness, and purity, found in the poems of Virgil, Horace,* and Cowper,† are not less worthy of our careful consideration and thoughtful reflection.

The speaker in the course of his statistical researches has so frequently observed the ill effects of city life,

* This used to be my wish : a bit of land,
A house and garden with a spring at hand,
And just a little wood. The gods have crowned
My humble vows; I prosper and abound.

Hoc erat in votis,—Sat., VI., B. II.

* * * *

The farmer dragged to town on business, swears
That only citizens are free from cares.—*B. L., Sat. I.*

* * * *

And courts and levees, town-bred mortals'ills,
Bring fevers on and break the seals of wills.

Quoniam dies tibi pollicitus,

† Strange ! There should be found,
Who self-imprisoned in their proud saloons,
Renounce the odors of the open field
For the unscented fictions of the loom ;
Who, satisfied with only pencilled scenes,
Prefer to the performance of a god.—*The Sofa.*

* * * *

God made the country, and man made the town,
What wonder then that health and virtue, gifts
That can alone make sweet the bitter draught
That life holds out to all, should most abound,
And least be threatened in the fields and groves.

—The Task.

But though true worth and virtue in the wild
And genial soil of cultivated life
Thrive most, and may perhaps thrive only there,
Yet not in cities oft ; in proud, and gay,
And gain-devoted cities, Thither flow,
As to a common and most noxious sewer,
The dregs and feculence of every laud.

In cities foul example on most minds
Begets its likeness. Rank abundance breeds,
In gross and pamper'd cities, sloth, and lust,
And wantonness, and gluttonous excess,
In cities vice is hidden with most ease,
Or seen with least reproach ; and virtue, taught
By frequent lapse, can hope no triumph there
Beyond the achievement of successful flight.—*Task.*

that he was led to inquire whether the noticeable decline in health, fecundity, and longevity of the human race, and of the American people in particular, were not due to the too great crowding into cities ; and he finds from an investigation of the subject that he is warranted in his belief.

That there is a well marked and fully appreciated decline in the health, fecundity, and longevity of the people of the United States, we have only to refer to the investigations of those of our fraternity who have given the subject much thoughtful attention, and are undoubtedly well able to judge. Among these, I may mention Dr. Nathan Allen, of Lowell, Massachusetts ; Dr. J. M. Toner, of Washington, D. C. ; Dr. John S. Parry,* of Philadelphia, and the late lamented Dr. Hunt,† President of the London Anthropological Society.

These men are all habitually careful, thoughtful, and, moreover, conscientious in the expression of their opinions ; and we are forced to accept the weight of their evidence, however humiliating, as regards our future prospects as a nation.

Dr. Parry believes that " it may yet become a serious question, whether the Anglo-Saxon race is adapted for life in this country with its variable climate ; and it may yet become a very serious question, whether the American will become a permanent nation, if immigration is cut off, for it is beyond doubt that though our people are not physically weak, the number of children born to native parents is small, and is decreasing every year. This is true not only of those families who have lived in this country for three or four generations, but it is more or less true of the immediate descendants of our Irish and German immigrants."

If William Barton were living to-day, he would find his predictions of fertility, longevity, and increase of our people had fallen sadly short of his high hopes, as expressed in a letter to David Rittenhouse, dated March 17th, 1791, " On the Probabilities of the Duration of Human Life in the United States of America."‡ He calls attention to the fact of the population having doubled in fifteen years ; while at the present time it will take more than twice that length of time to increase the population to the same extent, and this is only 82 years ago.

He attributes this unparalleled increase to the early marriages,§ virtuous habits, and simple manners of the people. The lack of large cities did not escape his notice, for he compares the unfavorable circumstances connected with city life with the healthful employments of the country.

The average duration of human life in Philadelphia near the close of the 18th century was above 28 years, now it is but 24.5 years.¶

Notwithstanding the fact that the mean average duration of human life has decreased apparently 3.5 years in our city (though in reality more), yet, strange to say, there is one person in every 33 of those dying who attain to 80 years and above, among those dying from

§ William Penn, in a letter to his friends in England, says that there is scarcely a maid of noble age unmarried in the Province of Pennsylvania. Need I say how different it is now? How many men and women remain unmarried !—*Watson's Annals of Pennsylvania*.

¶ See further in the author's paper on " Statistics Relating to Births, Marriages, and Deaths in Philadelphia for the eleven years ending December 31, 1872."—*Penn Monthly*, Sept. 1873, p. 24.

1860 to 1872; while there is but one in every 38 in the period from 1820 to 1830, and only one in every 40.8 for the years 1789 and '90,—above the age of 90, however, there was a larger proportion in the earlier periods than at present.

The fact of there being a larger proportion of persons above 80 years of age among the decedents in recent enumeration than among those taken some years previous, has furnished a foundation, in fact, on which some exceedingly clever men have based erroneous conclusions,—among which I may mention the seeming inference that the *average duration of human life* has increased.

Now this fallacy happens in the following manner, viz.: A certain proportion of those dying in the extreme ages mentioned are exogenous, having come to the city in late adult or advanced age, and though they contribute to swell the number, and consequently increase the proportion in extreme ages, yet their number is not sufficient to very materially affect, though falsely increasing, the mean average duration of human life, on account of the immense numbers dying in infancy and inferior ages. The reason that there was a larger proportion among the decedents of extreme ages in the decade from 1860 to 1871, than the decade between 1820-30, was because there was a larger proportion of persons of advanced ages coming into the city in the first-named decade than in the last. In the ten years from 1860 to 1870, 91,674 persons, strangers from other places, took up their residence in Philadelphia, and by far the greater part of them were adults. This paradoxical contradiction is repeated in respect to the poor of cities, among whom, though the mortality be greater and the average duration of life less than among the rich, yet they have a larger proportion of decedents of extreme ages than the latter class.

The fault of overcrowding cities with idlers is a mere matter of fashion. In America it is the fashion to live in cities. In England it is equally the fashion to live in the country. Yet there is a reason for this fashion—and it is principally a matter of money. We Americans have not wealth enough to live in the country—though it may seem paradoxical to say that it costs more to live in the country than in the city—but I mean to live fashionably, which must always include a town-house. In short, the people in America are utilitarians as yet, are too busy in making money, and have no time to do visiting at distances, and as a consequence country people would have no social life; their wives would have but one man to dress for, their daughters would languish in listless maidenhood, and their sons grow dull with *ennui*.

After a time, with more wealth, and when land is scarce and dear, it will become fashionable to have landed estates as the most solid and satisfactory investments. Thus, if not too late, we may reasonably hope that our citizens will be aroused to their interests and that of their posterity.

As a further evidence of more rapid physical degeneracy in great cities than in country districts, the *decline in stature* is a proof. Dr. J. Adams Allen* says: "In the United States the average height of persons bred and living in large towns and cities is something less than that of those living in rural districts." This fact is so noticeable that it need not be attested by actual measurement.

The most trying time for children in cities is during the intensely hot weather of the summer months, as may be seen from an examination of Dr. Russell's comments † on the dreadful mortality of children in New

York City, for the week ending July 6, 1872. During this week there were 1591 deaths in all, 229 more than ever before registered. 1,007 or 63.2 per cent. of these, were children under 5 years of age; and 45 of persons above 70 years of age. Of 1,007 infants under 5 years of age, who fell victims to diarrhœa, 499 were under 1 year, and 604 under 2 years.

The total mortality from diarrhœa was 653, or 41 per cent. of the deaths from all causes. Of the 2,351 deaths from all causes in the month of July, 140 were of diarrhœal affections, and 102 of diseases of the nervous system.

Intense heat, bad food, and foul air appear to be the principal predisposing causes to this extraordinary mortality. The "Free Camping Grounds and Sanitariums" recommended by Dr. Toner are assuredly worthy of consideration in this connection, as offering a means of obviating a large part of this extraordinary mortality.

In the United States (1860) there was one death to every 78.32 inhabitants, in 1870 one to every 79.77; while in New York City (1870) there was one death to every 39.3 inhabitants. In Philadelphia, 1861 to 1871, one death to every 39.1 inhabitants. Gen. Walker* gives the mean average duration of human life in the United States (1870) at 39½ years, while in New York and Philadelphia it is only 23 years, or 16 years less.

The mortality of great cities is found to be, both in this country and in Europe, more than twice as great as that of the rural districts; indeed it is fully 2½ times as great, for the cities are counted with the country in those comparisons, thus reducing the difference in their favor, and moreover, the mean average age at death in cities is falsely increased by the fact of the exogenous population of towns having passed the most critical period of their lives in the country.

On inquiry into the causes of the greater mortality of cities than rural districts, we find that circumstances connected with poverty are most noticeable, for in Philadelphia, during the 10 years ending 1871, I found that there was but one death to 57 inhabitants in the richest ward, though not exclusively inhabited by that class, and 1 death in every 42 inhabitants in the next richest ward, while there were but 36.50 inhabitants to every death, in the poorest ward, and there were but 4.86 persons to each family, and 5.04 persons to each house, here; while there were 6.23 persons to each family, and 7.04 inhabitants to each house in the richest.

Similar differences were found in Boston, in 1870, the year of the census.

Large towns have been emphatically called the *graves of humanity*, and certainly they are not favorable to health and longevity. Indeed, they might be very properly compared to the fiery furnace, into which the condemned children were cast.

Those who would live to a good old age, and hand their names down through a numerous posterity in children endowed with rich mental gifts, should avoid the dangers of the great city and choose the country life.

DEATHS FROM CANCER.—Among the 23 deaths from cancer, which have occurred during the past 24 years in the experience of one of our life-insurance companies, only one seems to have been hereditary. In this case the only other member of the family who appears to have had the disease was a sister.

† *New York Medical Record*, p. 333. 1872.

* Gen. Walker, in his address before the American Public Health Association, Nov. 12, 1873, said that he estimated the deficit in the returns of deaths in the census of 1870 at 33 per cent.

Original Communications.

TWO CASES OF FIBROID GROWTHS UPON THE VOCAL CORDS.

TREATMENT BY EXCISION AND EVULSION.—CURE.

By GEORGE M. LEFFERTS, M.D.,

LATE CHIEF OF CLINIC TO PROF. STOECK IN THE IMPERIAL UNIVERSITY OF VIENNA; SURGEON TO THE DEMILT DISPENSARY, ETC.

CASE I.—I. G. S., aged 31. Patient states that one year ago he had a severe cold, with cough, which lasted several weeks, and that the hoarseness which developed itself at that time, and which he had never before noticed, has gradually increased up to the present date, but that he has never suffered from complete loss of voice. His respiration has at times been affected, especially after prolonged exertion, but never to any marked degree.

He has occasionally had a cough, with expectoration of thick, grayish mucus. Deglutition has not been affected and his general health has remained good. Examination of his lungs shows them to be free from all disease. Has never had syphilis. At the time of the above attack he was treated for the hoarseness with medicated inhalations, but without relief. No laryngoscopic examination was made.

During the last two months his hoarseness has grown so rapidly worse that he is now nearly aphonic. On laryngoscopic examination I found a fibroid polypus of a bright-red color, and the size and form of a small cherry-stone, situated upon the free edge of the left vocal cord and partly overlying its superior surface. Its short pedicle was attached to the cord at the junction of its middle and anterior thirds. The neoplasm projected into the opening of the glottis, and, on attempted phonation, was seen to impinge against the opposite vocal cord, so that neither cord could advance completely to the median line, an elliptical opening remaining between them.

The true cords were congested and relaxed, the false cords swollen; and the mucous membrane throughout the larynx was hyperæmic and covered by a thick, tenacious mucus.

On the same day that the examination was made an immediate attempt at removal of the growth, without previous training of the larynx, was made, as advised by Prof. Stoerk, but was entirely unsuccessful, owing to the great irritability of the patient's throat. As immediate forcible spasm of the glottis followed each introduction of the instrument, after two or three trials the attempts were discontinued.

The following day an ordinary laryngeal sound was passed several times at short intervals, down upon the polypus; and the larynx in this case became so quickly trained to bear the use of instruments, that the operation for removal was at once proceeded with.

The instrument used was the guillotine of Prof. Stoerk, of Vienna, as recently modified by him, and which in its new form has not as yet, I believe, been described in the American journals. The modification consists in leaving the round fenestrated knife, which is ground plane on one face and concave on the other, and which was formerly entirely covered and concealed by a frame supporting it on both sides, unguarded except at its upper part, where it is covered by a small crescent-shaped sheath, attached to the end of the tube of the instrument.

The handle and mechanism of the modified guillotine are the same as in the old form, viz.: the tube of the instrument, bent at an angle of about 120°, terminates at one end in the crescent-shaped expansion mentioned above, which covers the upper third of the fenestrated knife; its other end is inserted into a handle provided with three rings, situated one above, one below, the third at the extremity of the handle.

The index and middle fingers having been inserted through the two first rings, the thumb is passed through the third, and by means of a simple closure of the hand the rings are drawn towards each other, and the knife-blade, connected with the rings by means of a wire passing through the tube, is drawn upwards until its inferior concave cutting edge meets the concave edge of the protecting sheath above, thus first clamping and then cutting through any growth which may have been introduced into its fenestrum.

The advantages claimed by Prof. Stoerk for this modified form over the old guillotine are: *

1st. That it is much lighter and occupies less room in the larynx, and in this lighter and more elegant form is much easier of adaptation to small growths, which were always difficult to seize with the heavier instrument. For large growths which have to be crowded into the fenestrated knife and require considerable force to cut them through, the large protected blade, supported on all sides by a circular sheath, or one of the many forms of *écarrasur*, must be used, and have shown themselves thus far to be the most suitable.

2d. That the protecting sheath of the knife in the old form covered a certain portion of the growth when placed in position over it, and thereby prevented its entire and complete removal at one operation; whereas with the new guillotine, the sheath being entirely dispensed with except over a small part of the knife above, the blade *itself* may be firmly pressed over the growth, and even be made to cut a line or two deeper into the vocal cord or part on which the polypus sits, in order that the operator may be certain that he has removed the entire base of the neoplasm. To do this, firm pressure is necessary; for the deeper the parts surrounding the polypus are pressed back, the further forwards into the fenestrated knife the body to be extirpated will come, and the less will remain behind of the pedicle or point of insertion, which fact will prove of great advantage during the process of healing.

3d. That when growths are situated on the vocal cords, near the anterior commissure of the larynx, the size of the sheath in the old form of instrument prevented its being passed between the growth and the commissure so as to encircle the polypus, thereby rendering the instrument useless for growths so situated. In the modified form, however, the light steel knife-blade presents no such obstacle. This modified instrument having been carefully passed into the

* Stoerk. Laryngoskopische operationen. Wien, 1872.

larynx in the above case, the patient was directed to take a deep inspiration, the glottis being thus well opened and a clear view of the growth, projecting as it did from the cord, obtained, after one or two unsuccessful attempts the fenestrated blade was pressed over it, and on being drawn up, cut the growth cleanly from the cord at its base.

The slight hemorrhage which followed ceased spontaneously in a few moments, and a few hours later it was hardly possible to recognize the former seat of the growth, the clean incision leaving no ragged edge or excavation to mark its site.

The following day the patient reported that his voice had improved markedly and was clearer than it had been for months; a laryngoscopic examination showed that the closure of the vocal cords during phonation was accurate and close.

A subsequent examination, three days later, showed that a very slight degree of inflammatory action had followed the operation and was confined to the left cord; a small ulcer, covered by healthy granulations, marked the former site of the polypus; voice remained clear and had improved in power. The remaining treatment of the case was directed mainly against the catarrhal condition of the larynx. The cause having been removed, this rapidly improved, and the following week the patient was discharged cured.

In concluding the history of this case it may be remarked, that only those growths which, from their situation on the free edge of the vocal cords, or which, from their particular location, project into the cavity of the larynx, and which are of a size to allow of either a partial or complete seizure within the fenestrum of the knife, are adapted for operation with the guillotine. Growths in other situations, such as the one in the following case, require the use of some other form of instrument.

In the practical application of the guillotine, care must always be taken to place the blade in the sheath in such a manner that the plane side of the knife be presented towards the side of the larynx on which the growth to be extirpated has its location; for the concave ground side does not permit of so exact an adaptation to the parts as its fellow, and hence the incision would probably not have the desired nor requisite depth to completely remove the neoplasm.

In comparing the relative merits of the guillotines of Stoerk and of his predecessor, Türk, it will be found that the former possesses many advantages over the latter, not only in form, but also in mechanism and the completeness with which the knife removes the growth. In Türk's guillotine* the knife is completely guarded by a heavy frame made either square or rhomboidal in shape, and therefore presenting angles which cause more or less irritation of the laryngeal mucous membrane during introduction into and withdrawal from the larynx. The knife, either lancet-shaped or with only one cutting edge, acts by being pressed forwards, and will be found practically rather to hack the growth than cut it through by one clean incision, the chances of which result are also much diminished by the fact that only one cutting edge presses upon the growth, while with the instrument of Stoerk it is encircled by a blade, which acts by being drawn upwards into its sheath, and the round and light form of which presents no difficulty nor obstruction either in its introduction or withdrawal.

CASE II.—J. P., aged 26. In January, 1871, patient, while drinking a glass of beer, suddenly felt an obstruction in his throat. Believing that he had swallowed

some foreign body, he introduced his finger into his throat as far as possible in order to remove it; this act was followed by vomiting, during which the sensation passed away. At this time he had neither difficulty of breathing nor cough, nor had he previously noticed any alteration in his voice. Immediately after, however, he observed that his voice was daily becoming weaker. The feeling as if a foreign body were in the throat returned at times, but the sensation was never as marked as on the first occasion. Respiration and deglutition have remained normal, and the patient has had no pain. The weakness of the voice increased at times even to complete aphonia. A physician was consulted a few days after the occurrence of the above attack, and examined the patient's throat (no laryngoscopic mirror was used), but discovered nothing; gargles and vapor-baths were recommended.

From this time up to February, 1873, no new symptoms made their appearance. The hoarseness gradually increased, with occasional variations; greater in winter, less in summer. The patient's general health has remained good, and he has been free from any local pain.

In February, 1873, while eating, the sensation as if a foreign body were in the throat suddenly returned. Patient describes the feeling as the same as that which he had at the beginning of his history. He again attempted to remove the supposed foreign body with his finger, upon which he had a severe attack of coughing and spat blood. Since then the hoarseness has rapidly increased, and for the last two months he has been completely aphonic. For the first time he has had pain, constant and aggravated by swallowing; no cough.

Status præsens.—Patient speaks in a whisper. His attempts to raise the voice are in vain. He complains of pain, increased by pressure over the larynx, and of a constant sensation as if some foreign body were lodged in his throat. On examination, pharyngitis; larynx large and well formed; epiglottis congested; false cords swollen and reddened; the vocal cords congested anteriorly. On the right vocal cord, in its middle third, is situated a fibroid polypus the size of a pea; it is almost spherical in form, and of a bright-red color. The pedicle is small, and springs partly from the upper surface and partly from the edge of the cord. The greater part of the polypus projects into the opening of the glottis during inspiration, and assumes a conical form, with its apex directed towards the opposite cord. During phonation the left cord approaches the median line and lies perfectly straight; but the right cord, prevented by the obstruction which the intervening part of the polypus occasions, cannot touch its fellow and shows a concavity. At the same moment the polypus is pressed upwards, and lies to a great extent upon the cords.

The movements of the adductor muscles of the cords are irregular and unequal. Instead of the rotation of the arytenoid cartilages being equal and simultaneous, the left cartilage is rotated much more quickly and energetically than the right, which occasions the left

* Türk. Krankheiten des Kehlkopfes. Wien, 1866.

cord to lie over the median line towards the right side of the larynx. The right arytenoid cartilage revolves more slowly and approaches its neighbor, while the right cord assumes a crescentic shape, inasmuch as it is prevented from reaching the opposite cord by the intervening part of the polypus. As the largest part of the polypus lies upon the vocal cords during phonation, and as its base is attached to the upper surface of the left cord, the case is not adapted for operation with the guillotine, nor any of the forms of crushing forceps of Türk. The polypus must be removed on the same principle as if it were a foreign body lying upon the cords; that is, it should be seized from above with the laryngeal forceps and torn from its attachment. The lower portions of the polypus being pressed between the vocal cords during phonation, renders the upper and greater part tense, and thus affords a prominent object for, and a firm hold to, the instrument.

Operation.—A short time was devoted to training the patient's larynx to bear the introduction of instruments. This was done by means of the laryngeal sound, and the desired result was quickly obtained; mainly, however, owing to the fact that on the previous day he had been examined by a number of medical gentlemen, and a tolerance of instruments had been thus established which markedly assisted the operative procedures. The instrument used was the tube-forceps of Türk. After having passed them over the epiglottis, before entering the laryngeal cavity, the patient was directed to phonate E as loudly as possible. By this means the cords were rendered tense and the greater part of the growth forced up upon them, and plainly to be seen; the instrument was then passed quickly down upon it, and on the first attempt it was seized and more than two-thirds brought away within the grasp of the forceps. The remaining portion lay upon the vocal cord, near its edge, and appeared to consist mainly of the pedicle. As this remainder was very small and partly hidden by the small clots of blood which quickly formed, its removal gave considerable trouble, and it was not until after several vain attempts that it was accurately seized and brought away. The hemorrhage which followed the operation was trivial in amount, and was quickly controlled by means of ice. An examination, made a short time subsequently, showed that the whole of the polypus had been removed, its former seat being indicated by a shallow excavation on the edge of the cord and a small excoriation upon its upper surface. The operation lasted in all three-quarters of an hour.

An examination made two days later, showed a small ulcer covered by a grayish secretion over the site of the polypus, and in its immediate neighborhood were several small extravasations of blood. At this point also the edge of the cord was irregular, some of its ligamentous fibres having probably been cut through. The closure of the cords during phonation was much more perfect, only a very small elliptical opening remaining between them. The voice was clear and had increased in power, and the sensation of a foreign body in the throat had disappeared. The slight degree of inflammatory action excited by the operation was rapidly disappearing.

The subsequent history of the case, with the exception of a slight relapse of the inflammatory symptoms, brought on by exposure, was satisfactory and rapid in its progress towards a complete cure. The case remained under observation for two weeks, during which time the ulcer on the cords was twice lightly touched with the nitrate of silver; but no other treatment was pursued nor considered necessary. The

patient's voice improved daily in strength and clearness; and at the last laryngoscopic examination, made before his discharge, the closure of the vocal cords in phonation was seen to be regular, accurate, and close.

A still better instrument than the one used in this case, and which would have been on some accounts preferable had I had them at hand, are the forceps of Mackenzie or Fauvel. The principle is the same as in the tube-forceps of Türk, which were used; the growth is cut or crushed off from its seat, but the form of the instruments renders them much easier to use, and more certain when attempting to grasp the growth. The breadth and strength of the blades in the first forceps makes an operation similar to the above comparatively easy, as they, if once placed near or over the growth and then closed, are almost sure to grasp it, such is the extent of surface which they cover in the larynx. The growth once grasped, is immediately cut or crushed off, and the portion removed comes away enclosed between the blades of the forceps.

The only objection to the instruments is the difficulty, on account of their size and form, in introducing them into the larynx without causing spasmodic action of the patient's laryngeal muscles, and thereby preventing completely, after introduction, any more than a momentary clear view of the growth to be extirpated or the position of the forceps, unless the patient has been previously trained to bear their use.

This objection can be partly remedied by studying well the location and surroundings of the growth before attempting to introduce the forceps; and after the latter are well over the epiglottis, and if possible over the growth, before laryngeal spasm is excited by touching any part of the larynx, carrying them quickly to the desired point, which will in the majority of cases be safely reached, even if the last stages of the introduction be obscured by the closure of the laryngeal walls about the instrument. It may here be remarked that Jelenffsky, of Prague, relies entirely upon his "tactus eruditus" and anatomical knowledge of the larynx, and familiarity with the location of the growth to be removed, when attempting to extirpate it, and does not endeavor to see the point of his instrument after it has once passed into the larynx.

It is, however, needless to say that this latter method of operating cannot be considered as elegant or skillful, nor even safe.

It is of course always to be borne in mind, not only when using the above form of forceps, but also any of the other forms of laryngeal instrument, that the smaller the growth, the greater is the play given to chance in attempting to seize it, and the greater is the amount of manual dexterity required.

The drawings accompanying the histories were taken by me from nature at the time of the operations, and represent accurately the size, form, and location of the growths.

323 WEST TWENTY-SECOND STREET.

ESMARCH'S BLOODLESS OPERATIONS.

WITH REMARKS.

By ROBT. F. WEIR, M.D.,

SURGEON TO ST. LUKE'S AND THE ROOSEVELT HOSPITALS.

In a lecture recently given by Prof. F. Esmarch, of Kiel, published in September, 1873, in Volkmann's *Sammlung Klinischer Vorträge*, and subsequently translated in the London *Medical Record* for Oct. 29th, 1873, is given at length a procedure adopted by that distinguished surgeon to prevent loss of blood during surgi-

cal operations. To effect this, the limb—for the method is confined to operations on the extremities, and external male genitals—is enveloped in oiled silk or rubber tissue, and a bandage made of india-rubber webbing is applied tightly from the fingers, for instance, to a point just above the situation of the proposed operation, where a piece of india-rubber tubing is drawn, strongly stretched, around the limb four or five times, and secured by hooks previously fastened into each of its ends. The elastic bandage and oiled silk or varnished tissue-paper are then removed, and the limb is seen as pallid as that of a corpse. The operation is then proceeded with, with probably the loss of not more than a teaspoonful of blood. (In an amputation of the thigh by Dr. Sands, at Bellevue Hospital, a few days since, only 11 drops of blood were lost, by actual count.) This procedure has been used, Esmarch says, by himself for some time,* and although he does not claim the originality of it, as Silvestri, Langenbeck, Stromeier, Erichsen, and others abroad, and in this city the surgeons of the N. Y. Hospital, had been in the habit of bandaging strongly the limb prior to amputation, first stroking it upwards to empty the veins, yet it is evident that its present perfection is due to him alone. Its merits have been tested in England by MacCormac and others, with excellent results, and in this city first by Krackowizer, and subsequently by others. Here, the rubber-webbing employed has either been such as is used for suspenders, or, what is better, from being thinner and more easily applied, strips of shirred rubber† 1½ inches wide and 3 yards long. Three of these bandages suffice for a thigh amputation.

For the waterproof varnished tissue-paper used by Esmarch, oiled silk or thin rubber sheeting (not vulcanized cloth) has served as well, nor has it been found necessary to secure the ends of the tubing or solid rubber cord by hooks, as simply securing them by a surgical knot has answered. In contrast to the case of amputation of the thigh by Dr. Sands, mentioned above, another surgeon tried the plan of tightly compressing the limb with ordinary muslin bandages, applying the tourniquet, removing the bandages, and then performing the required amputation. The result showed most decidedly the superiority of Esmarch's method.

This method has been four times resorted to during my present service at St. Luke's Hospital, once for necrosis of the humerus, where nearly the whole length of the bone was removed with loss of, at most, a teaspoonful of blood, where, as a result, the living involucrum appeared nearly of the same whiteness as the dead bone. The operation was completed after Esmarch's plan in such cases, that is, to line the cavity with a layer of gauze, moistened with a solution of chloride of iron; this is packed tightly with German tinder, and in the case at St. Luke's Hospital by charpie soaked in carbolic oil, and the whole limb next enveloped in oiled silk, secured by firm pressure of a gauze carbolicized bandage. Not until the dressing is finished is the constricting rubber cord or tubing removed. In this way is the loss of blood reduced to a minimum. Although in amputations such dressings cannot be resorted to, and, as in the second case—amputation at the wrist-joint—it was found that after all the perceptible bleeding-points had been secured and the tubing removed, considerable oozing occurred from minute vessels, just as it would after removal of the ordinary tourniquet. In the other cases, viz., syphilitic necrosis of the radius and Syme's amputation at the ankle-

joint, the bloodless character of the operation was also thoroughly maintained.

The experience obtained in London and in this city has already been sufficient to enable the profession to accept the method as a marked surgical improvement, though the restriction placed on its employment by its celebrated promoter,* in cases where there would be danger of forcing septic material into the lymphatic circulation, is eminently just, and should be kept prominently in mind.

19 EAST THIRTY-SECOND STREET.

FIVE CASES OF CEREBRO-SPINAL MENINGITIS IN THE SAME FAMILY,

PRESENTING PECULIAR PHENOMENA.

By W. W. MUNSON, M.D.,

OTISCO, N. Y.

WILLIAM S., a large, fat, German boy, aged 16 years, weight 215 lbs., previously healthy, applied to me for treatment Sunday, July 27, 1873, complaining of diplopia and obscure vision, some little pain over the eyes, and slight feeling of obstruction in throat. Not feeling as well as usual for two days past, but has kept at work. First felt a little indisposed Friday, 25th, but worked in the hay-field all day. Was at base-ball play Saturday, 26th, where he seemed to see two balls flying in the air when there was but one. I considered it a case of ordinary cerebral congestion, from being overheated and overworked, and prescribed cathartic at night, bromide potass. gr. xx. in aq. camph. t. i. d., middle of forenoon, middle of afternoon, and at bedtime. Recommended rest and to avoid exposure to heat of sun. Advised him to return in two or three days if no better, and be bled, as this appears to be a proper case for bleeding, if any.

Monday, 28th.—Called to him in great haste, with report that he was choking. See him about 6 A.M., and find that in trying to swallow some water he was strangled by a portion dropping into the larynx. In examining throat in ordinary way—pressing down tongue with spoon-handle—I induced another attack of spasm of glottis, which lasted during four or five respirations. Ask him to swallow some milk, which he does with great difficulty, taking but a few drops at a time—liquid rushing out of mouth and nose if he undertakes to swallow too much. No appearance of disease in throat. Not hoarse. No difficulty in breathing, only when choked by attempting to swallow something. Able to move eyes and eyelids but very little. Can see very well, but everything appears double. Countenance stolid and expressionless, as is the case in double facial paralysis. Can get up and down easily. No loss of use of any muscles other than those about face. No febrile movement. Pulse accelerated, but weak. Evidently great disturbance at origins of cerebral motor-nerves, but I am unable to make the diagnosis, to name the disease, especially as a little sister of his, four years old, begins to present the same symptoms. His phlegm given last night has not operated. After great effort he swallows another pill. Call for council. Dr. Earl, of Tully, arrives at noon. We cannot make a diagnosis. Send for further council. Patient cannot swallow anything without inducing strangulation. Complete paralysis of muscles of pharynx. Being very plethoric we take a pint or so of blood

* From January 1 to August 15, 1873, 87 operations, of which 27 were amputations and disarticulations, 8 resections, 13 for necrosis, etc.

† To be obtained at Shattuck & Binger's, 18 Spruce st., New York.

* For Silvestri, of Vicenza, had used the rubber bandage and tubing before Esmarch.

from arm, with no apparent effect for better or worse. Little girl's symptoms increasing in gravity—cannot swallow. Dr. Dana, of Cortland, arrives about 5 P.M. The possibility of this being masked diphtheria, in which the nervous centres are overwhelmed without local manifestation, is fully considered, as an endemic of that disease has recently run its course in this section. Not knowing what else to call it, we wash out lower bowel, and administer quinine, tr. mur. iron, and whiskey by rectum in large doses—both patients being unable to swallow. Keep up this treatment through the night.

Tuesday, 29th.—6 A.M., both patients continue to fail. No pain anywhere. Boy unable to move eyeballs or eyelids a particle. Raises lids with hand when he wants to see anything. Sensation in paralyzed parts unimpaired. Intelligence perfect. Recognizes all who come in. Has no use of lips, tongue, or pharynx. Cannot spit, hawk, blow nose, swallow, raise corner of mouth, or use any muscle about head or face. Can turn head slightly. Has perfect use of all other muscles of the body. Pupils greatly dilated. No spasm or contraction—not so much as a quiver of a single muscle. Both children continue to fail during the day. Only one of girl's eyelids paralyzed, but symptoms are generally same as boy's. Inject $\frac{1}{2}$ gr. sulph. strychnia under skin of nucha of boy without response.

The father and mother of these children begin to complain of similar symptoms. Consider their sensations sympathetic, as they keep about, taking care of the children as usual, but give cathartic and tell them to keep quiet. Both children continue to fail, without any new symptoms presenting. Boy dies at 3 A.M., 30th, and girl at 5 P.M. same day, without diagnosis being made.

The parents and another daughter, 17 years old, complain quite seriously of these strange symptoms to-day (30th); but as they have been constantly watching over the other two for three days and two nights, and they keep up well, I am still inclined to consider their symptoms more sympathetic than real; but Dr. Earl (whom I have to thank for standing by me through this trying ordeal) looks upon them as purporting mischief.

Dr. Benedict, of Syracuse, whom we had sent for, arrived about an hour after the death of little girl, and from our description of the cases pronounced the disease *cerebro-spinal meningitis*. I rebelled against the opinion—could not believe in the existence of meningitis without spasm or contraction, headache or vertigo, pain or hyperæsthesia, delirium or coma.

But on examining upper part of spinal cord of little girl, within two hours after death, we found the dura mater highly congested, vessels of arachnoid and pia mater distended with blood, arachnoid cavity and subarachnoid cavity filled with serum. Brain not examined, as we had, in the condition of the cord, abundant evidence of the nature of the disease.

On carefully examining the other cases, they all complain of diplopia and dysphagia as chief symptoms, although pupils were dilated, tongue coated with a thin translucent pellicle, capillary congestion about face and neck, slight tenderness on pressure over nucha. They are evidently attacked. On the advice of Dr. Benedict we gave them two drops of croton-oil all around, following, as soon as practicable, with 20 gr. doses of sulph. quinine, alternating with full doses of fl. ext. nux vomica every twelve hours. Blister back of necks and put them to bed.

I at first questioned the use of strychnine, it being such a powerful cerebro-spinal excitant; but as Dr.

Benedict correctly remarked, the condition is more of a *congestion* than a true inflammation. The patients were all of that bilious-lymphatic temperament in which the circulation is sluggish. What we wanted was (1st), a remedy to relieve the congestion, which we had in quinine, and (2d), a remedy to *rouse* the circulation in nervous centres—not to reduce it—which we had in strychnine.

Without continuing the history of each case in detail, I will simply state that the daughter was not very sick, and perfectly recovered in ten days. The father became worse. For a few days he could not stir the eyeballs a particle; but he happily passed into convalescence and recovered in about three weeks. The mother also made a good recovery, but her case lingered somewhat longer. In her case double vision was complained of only when she turned eyes to one side. She also had partial loss of power of right arm for a few days. All were constipated. Considerable pharyngeal secretion in all from the start. Throughout their sickness the treatment was essentially as commenced. Necks were kept sore, while quinine and nux vomica were continued to the end.

As far as I am informed, by reading, observation, and inquiry, the phenomena present in these cases of meningitis are unique, all the prominent characteristics heretofore observed being replaced by symptoms entirely the reverse; the most prominent symptom in our cases being *paralysis*, without spasm, contraction, pain, hyperæsthesia, delirium, or coma in a single one of the five cases.

No sufficient cause for the disease in this particular family has been discovered. The family are intelligent Germans. Their house and surroundings are in as good hygienic condition as the majority of farmers' establishments hereabouts. No more cases of the disease have appeared in this section.

Previous to their sickness this family were in the best of health—well known among their neighbors as being specially strong and robust—and consisted of—

Father,	aged	38 years,	weight	210 pounds.
Mother,	"	40 "	"	250 "
Daughter,	"	17 "	"	170 "
Son,	"	16 "	"	215 "
Daughter,	"	14 "	"	207 "
Daughter,	"	4 "	"	40 "

All had the disease except second daughter, who was living away from home at the time the family was attacked, but remained with them during their sickness. The son and youngest girl died.

AN UNUSUAL TYPE OF EPIDEMIC COLITIS.

By S. T. CLARK, A.M., M.D.,

LOCKPORT, N. Y.

DURING the months of August and September of this year (1873), in Niagara County, especially in the town of Royalton, have occurred numerous cases of colitis of an unusual character, not described in any authority with which I am conversant, and, as I think, of sufficient interest to engage the attention of the readers of THE RECORD.

The invasion was sudden, the person attacked was seized with a chill of great severity and long protracted, accompanied with such prostration as one sees only as the result of internal hemorrhage. The chill gave place to a febrile stage, and, as the pulse became accelerated and the temperature increased, the most in-

tense pain was experienced in the right iliac fossa: the patients described it as lancinating—as if thrust through with a sharp knife—and this pain was attended with nausea, but no vomiting. The febrile stage was short in comparison with the chill, and ended in a profuse discharge of *fluid blood from the bowels*, an ordinary bed-vessel being half filled at the first evacuation.

From this time until convalescence was fully established, the fever, pain, tenderness, and diarrhoea were constant. After the first profuse evacuation of blood the small discharges from the bowels were of a typhus, beef-brine character, and very offensive. It was not uncommon to see perfectly natural fecal matter voided immediately before or after the typhus stools.

The tongue did not become dry or coated until after twenty-four hours, and then not more so than the administration of large doses of opium invariably produces. No sordes collected upon the teeth; many retained their appetite for food; the abdomen was never tympanitic, or the urinary secretion disturbed; no tenesmus, no borborygmi, nor mucous discharges; showing that the seat of disorder was that portion of the colon immediately below the ileo-cæcal valve. Large doses of opium were tolerated, indeed indispensable in controlling the pain, and with the relief of this the nausea disappeared.

Astringents seemed to aggravate the symptoms, increasing the fever and pain, and producing disagreeable cructations.

Turpentine, exhibited externally or internally, failed to mitigate the severity of any of the symptoms which it so universally relieves in enteritis and enteric fever. Calomel in minute doses had no control over the nausea.

The largest number of cases treated by an intelligent observer (thirty or more) occurred in the practice of Dr. D. H. Murphy, who relied on the following formula almost entirely:

R. Pulv. opii ℥iiss.
 Quinine sulph.,
 Piperine,
 Pulv. zingiberis.....āā ℥i.
 M. Ft. chat. No. xx.

He gave adult patients a powder every four hours, and continued as long as medication was necessary, increasing the interval between doses, but not lessening the quantity.

In the cases in my own practice I discovered no benefit from quinine, but a marked promptness with which the opium controlled the pain when combined with the *pungent aromatics*. I used capsicum with the opium and alcoholic stimulants, and diet of butter-milk when procurable.

The duration of the disease was rarely less than eight, and often eighteen, days; relapses *always* occurring.

After the opium treatment had been continued forty or forty-eight hours, and the patient had taken ten or twelve grains of the drug, the improvement was so sudden, the cessation of pain and morbid discharges so complete, the return of strength and spirits so decided, and the appearance of the patient so natural, that the medical attendant was often dismissed; but always recalled; for, at that period of the disease, the withholding of a single grain of opium for four hours was invariably followed by a reappearance of all the symptoms, and often with *increased severity*. When genuine convalescence was established, every case was marked by a most obstinate constipation. This, at first, I was disposed to attribute to the long and liberal use of opium; but soon became satisfied that it was conse-

quent upon either a thickening of the mucous membrane at that part of the bowel which was the seat of inflammation, or a loss of the muscular and nervous power at the same point, and most likely both, for the energetic administration of enemata, digital examinations per anum, and the introduction of the rectal bougie, demonstrated the absence of scybala.

Time and rhubarb, with strychnia, prudence in diet, and plentiful out-of-door exercise overcame this vexatious sequela.

This disease of the colon was not confined to any class or age, but generally passed through the family and seemed to spread from house to house in a neighborhood by the members of one family watching with the sick of another, and who were attacked in a week or ten days after the first exposure.

The fetid discharges seemed to be the medium of communication, and the free use of carbolic acid a great protection. A Mr. G., who visited a family in Royalton, where the lady of the house, Mrs. W., was suffering most severely from this disorder, and so completely prostrated as to be totally unable to help herself, and being of about 200 pounds weight, it was usual for some male member of the family to assist in nursing her, he remained a portion of one night in her room, and the next day returned to his own home in Canada, nearly or quite a hundred miles distant, and in ten days' time was seized with this form of fever, and his entire family after him. Fortunately, in the practice of regular medical men, this disease was not fatal, so that the opportunity of an autopsy has not occurred. One or two very aged persons, apparently from the same causes, have died of typhoid dysentery, and very suddenly. In these cases the inflammation extended from the *rectum* to the *ileo-cæcal valve*. In the hands of quacks a few cases died from the long-continued exhaustive discharges, and the cases were called typhoid fever; but I do not learn that the abdomen in any case has been markedly tympanitic, that there has been delirium, headache, fæculation, rose-colored eruption, sudamina, deafness, cough, or bronchitic râles in any case, and the tolerance of anodynes was quite the reverse of that usual in *any* but *acute* inflammations of the bowels.

MULTIPLE STRICTURES OF THE URETHRA TREATED BY ELECTROLYSIS.

By T. F. FRANK, M.D.,

TITUSVILLE, PA.

Mr. H. L. McC., of Oil City, Pa., while participating in the raising of a liberty pole at Titusville, Pa., in 1869, was contused at the perineum by the falling and subsequent rebounding of the pole. Immediately after the accident he experienced some difficulty in micturition, which shortly after resulted in complete retention. Drs. Moody and Barr, of this city, relieved him at different times by catheterism until partially recovered, and he returned to his home.

Upon leaving this city the patient was advised by his physicians to follow the use of bougies, at intervals, till restoration of the urethra should be accomplished. Unfortunately, however, he neglected to act upon this advice, and remained a sufferer.

When he presented himself at my office, Nov. 13, 1872, the following conditions were ascertained, viz.: meatus urinarius too small for the introduction of a No. 8 bougie à boule; micturition excessively painful, and performed only by drops; urine loaded with glairy

pus, and blood-corpuscles in abundance discernible under the microscope. According to the patient's statement, he had not emptied his bladder during the past two years at any one attempt.

I placed him in the lithotomy position, and enlarged the meatus to such an extent with the electro-caustic knife, that a No. 12 bougie à boule could be passed through it and into the fossa navicularis. Continuing to push the instrument gently onward, I met a stricture resisting progress, about two and one-half inches from the meatus.

A No. 1 gum-catheter was the largest I could enter the opening with, and use for deeper exploration. Two inches from the first obstruction I encountered a second, and this so narrow that even the smallest filiform whalebone bougie could not be passed through it.

The patient was not under the influence of ether, and became restless and desired further proceedings to be delayed. I should here mention that I learned from Mr. McC. that, a few weeks previous to his visit to my office, several attempts had been made by two eminent surgeons in Philadelphia to enter the second stricture with the smallest bougies, but without success.

On Nov. 15th he came prepared to undergo any operation I might suggest for his relief; and after relating to him several cases of strictures successfully treated by me with electrolysis, he at once consented to the operation.

Having placed him in the same position as during the examination, I introduced an electrode (equal in size to a No. 10 bougie) into the urethra and as far as the first stricture, and connected it with the negative pole of a twenty-cell zinc and carbon battery; the positive, with a large sponge moistened with warm salt-water, being fixed to one of the thighs. While the assistant in charge of the battery gradually increased its intensity, I held the electrode firmly against the stricture.

When nine cells had been brought into the circuit, and at that strength applied for quite fifteen minutes, the pain became unbearable, and I discontinued the operation.

No unpleasant symptoms being manifested, on Nov. 17th I operated again, and in the same manner as heretofore described; but in five minutes, and while only eight cells were in action, the electrode passed through the stricture. After the removal of the urethral electrode I introduced a No. 12 gum-catheter as far as the second obstruction without any difficulty, and then ordered a repetition of the operation daily, during one week.

Nov. 26. Patient in a cheerful state of mind; had no difficulty in introducing catheter, and expressed himself ready for another operation.

The same electrode as previously described was connected, as during my former operations, and placed against the second stricture. When ten cells had been applied for a few minutes, the operation became very painful and was discontinued.

That night, after the patient's return to Oil City, he had severe chills, and a return of them daily, during one week. Dr. Egbert, of that city, attended him, and, by efficient treatment, so far restored him that I was able to go on with electrolysis on Dec. 6th.

At this time I had the battery-current so gradually increased that an hour was consumed before fifteen cells had been brought into the circuit. During this operation the patient experienced no inconvenience whatever; consequently I repeated the same treatment every other day till Jan. 21, 1873.

On that day the electrode passed through the stricture, and with little effort was pushed into the bladder,

after the current had been broken. Immediately after the removal of the instrument the patient passed a full-sized stream of urine, which he had not been able to do for more than two years.

No further electrolytic treatment being required for the present, I advised the use of No. 10 and 12 gum-bougies at one week's interval for an indefinite period, to insure permanent restoration of the urinary canal, as far as that could be accomplished under such circumstances.

From that time I saw nothing of Mr. McC. till October last, when he called upon me on his way home from New York. He had followed self-catheterism regularly as directed, to the day of his visit; but thought it unnecessary now to continue it longer, as he experienced no difficulty whatever during micturition. He had gained twenty-five pounds in flesh since the last treatment, and all former traces of cystitis had disappeared. I therefore dismissed him cured.

In connection with the former statements, I omitted to mention that the second stricture was ascertained to measure one-quarter of an inch in length, while the first I estimated to be of the linear kind.

While the result of my treatment in the above case is exceedingly gratifying to myself, I hope its publication may prove suggestive to surgeons who have tried electrolysis for the reduction of strictures with less success, to persistency in their applications, when such may be justifiable.

DR. LEAMING'S VIEWS ON RESIDUAL AIR AND SUBCREPITANT RALE CRITICALLY CONSIDERED.

By WILLIAM C. GLASGOW, M.D.,

ST. LOUIS, MO.

DR. J. R. LEAMING, of St. Luke's Hospital, New York, in a paper read before the New York State Medical Society, February 5th, 1873, reprinted in the March number of Dr. Brown-Séquard's *Archives of Scientific and Practical Medicine*, presents some new and novel views on "residual air" and the "production of the subcrepitant rale," which, if true, would certainly tend to disorganize and sap the very foundations on which the principles of physical diagnosis are established.

Any new theory, seeking general recognition, and which conflicts with the generally accepted opinions of auscultators, should be founded on sound facts supported by logical conclusions. To establish exactly the amount of residual air in the lungs is, it appears to me, a physical impossibility, and we can only therefore theorize as to the quantity. The favor or disfavor with which a certain theory will be received depends, of course, upon the fact whether we can or can not, in accordance with it, explain satisfactorily the sounds which we know arise within the pulmonary structure; and when we find that the acceptance of the theory will render the production of these sounds physically impossible, we must hesitate, and, however great the authority of its author, reject it. We may be wrong in our views as to the production of these signs. If so, it lies with the "theorist" to explain them.

As Dr. Leaming, by the publication of his theory, has challenged criticism, I propose, in the following brief paper, to prove not only that the premises are incorrect, but also that the conclusions are illogical and unsound; and this I do with great respect for the distinguished author of the paper whose views I controvert.

He says: "All the true respiratory system—that is, all of that part of the lungs which is beyond the third and fourth divisions of the bronchi—is persistently filled with residual air;" and, as a consequence of the acceptance of this proposition, we shall be compelled, of course, to abandon all the established theories of the production of certain of the respiratory phenomena, now believed to be produced in the smaller bronchi. Dr. Leaming seeks to explain the production of one of them, namely, the subcrepitant râle, by withdrawing it from the pulmonary, and making it an "*inter-pleural*" sound. Let us first, then, consider his statement in regard to "residual air." The idea of residual air precludes, of course, all idea of air *in motion*,—at least of all motion necessary to the production of sound,—and hence the extending of the residual air into the bronchi of the third and fourth calibre destroys, at once, the factors necessary for the production of all respiratory phenomena arising within the smaller bronchi. Now let us examine some of these phenomena, and the conditions producing them. *First, the normal vesicular murmur.* The inspiratory sound of normal vesicular murmur is produced by the passage of air through the terminal bronchi into the air-vesicles; whether explained by the theory of *oscillation* (Niemeyer), or by that of *friction* (Laennec, Scoda, Stokes), matters little. Were the bronchioles filled with residual air, there could be, of course, no motion, at least not sufficient to produce a sound; as Dr. Leaming himself allows, when he says, "there is no motion within the residual air of any force or velocity in any direction—no movement at all, except the molecular, which is silent; *there is no need of any other!*" If there is no "need" of any, will Dr. Leaming please explain the production of normal vesicular inspiration? Can we have a "silent" murmur? He may possibly have some views upon this subject with which I am not familiar. Perhaps he is a disciple of the "*système de retentissement*" of Chomel, claiming that the vesicular murmur is only a conducted weakened tracheal sound, thus overlooking the experiments of Chonveau, which conclusively prove the existence of vesicular murmur, the trachea having been divided between the first and second cartilages.

The same "need" of air *in positive motion* is required in explaining the crepitant râle of pneumonia, the prolonged expiration of emphysema, and the sibilant and subcrepitant râles of bronchitis; and unless these can all be logically explained in accordance with his theory, it must fall to the ground.

Appreciating, in part, the difficulties appertaining to such an explanation, he takes up the subcrepitant râle, and disposes of it in a summary, and, to him, doubtless, conclusive manner. He says: "The true mechanism of subcrepitant râle is always *inter-pleural*, and depends upon the presence of exuded lymph. True mucous râles, even when present, are not heard in the presence of plastic râles, for the exudation cuts off sound from the lung as effectually as closing a door!" Has Dr. Leaming never, in his large clinical experience, heard vesicular or broncho-vesicular sounds in cases of pleurisy, in which, judging from marked and acknowledged friction sounds, the pleura was covered with fibrinous exudation? If he has not, his experience is unique, and certainly not that of the majority of clinical observers.

He again says: "I have never failed to find plastic exudation after death as cause of râles heard in life."

That adhesions of the pleura are one of the most common of *post-mortem* appearances, no one can deny; but does Dr. Leaming mean to affirm that, in every case of resolving pneumonia in which the "*râle redoublé*" is heard, or in every case of capillary bronchi-

tis, even in infant life, in which the subcrepitant râle is present, there is plastic exudation on the pleura? A strange assertion, it would seem, but his words are to this effect; an assertion, however, with which the clinical and *post-mortem* experience of others is surely not in accord. In referring the subcrepitant râle to the "*pleura*," I think it is Dr. Leaming, and not the general medical world, who "misinterprets" the sound. That there is sometimes a great similarity between the true subcrepitant râle and an inter-pleural sound, I would not deny; and it requires, at times, the nicest precision of a practised ear to discriminate, by the sound itself, whether it is pleural or pulmonary. Still, this is no reason why the two sounds should be confounded.

Sounds may be produced on the pleura covered with fibrinous exudation, whenever there is motion of the pulmonary on the costal pleura; and the character of the sound will depend upon the condition of the membrane, whether dry or moist, and upon the character of the motion, whether sliding or perpendicular. If the movement is free and the membrane is dry, we shall have the ordinary rubbing, or, when limited by adhesions, the dry *crackling* sounds. If the movement is perpendicular, and the membrane is moist, we shall have the *moist crackling*. By perpendicular movement I mean when the two planes of the pleura are brought in contact in a perpendicular manner; and this can only be the case when they are so bound by adhesions, that the normal sliding motion is impossible.

The lung expanding on inspiration, the free surfaces (between the adhesions), covered with an adhesive fibrinous exudation, are brought in contact, and, separating during expiration, numerous moist bubbling sounds are produced,—sounds somewhat resembling the crepitant râle, only *exaggerated and intensified*, being produced under similar conditions. I believe this same moist crackling râle to be the sound mentioned by Walsh as "a medium-sized rhonchus, occurring in puffs, having a liquid bubbling character," but whose production he does not clearly explain; and it may be that these moist and dry crackling sounds, thus alluded to by Walsh, have been "misinterpreted" by Dr. Leaming as the "subcrepitant râle." They occur under the same conditions in which he claims to have found the subcrepitant, and, taking the four cases presented by him, we find all the necessary factors for their production.

Although Dr. Leaming's great skill as a diagnostician, and his reputation as a cautious observer, demand for his views most serious and respectful consideration; still, he must acknowledge that a satisfactory explanation, in accordance with his theory, of all the physical signs of auscultation, will be demanded before his novel views,—which must be regarded at present as purely speculative,—can be accepted by the medical world.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

STRUMOUS CHILDREN.

This class of cases embraces those children who seem to be favored with eczematous eruptions, conjunctivitis, glandular enlargements, and exhibit in gen-

eral a predisposition to inflammatory affections, especially of mucous membranes; and whatever the manifestation may be, they have a tendency to run a slow course. In such cases, if the child has any form of eruption, such as eczema capitis, it has a tendency to become confluent and pursue a chronic course.

In the treatment of these cases it is of the highest importance that the children should have the influence of sunlight and fresh air. It is said to be impossible for children to remain within a hospital for any considerable length of time without having scrofula developed.

This class of patients also requires a large amount of nitrogenous food, which is best supplied for young children by keeping them chiefly upon a milk diet. These points cannot be too strongly insisted upon.

The following prescription has been found to be of great service in the therapeutical management of these patients, although it is not an elegant chemical combination:

R. Syr. pyrophosphate of iron,
Syr. lacto-phosphate of lime, ʒā.
M.

Teaspoonful three times a day.

In the use of this combination, experience has proven itself a good schoolmaster, and the children do well under its influence.

PNEUMONIA.

A case of this common disease was seen which presented some features not very commonly seen. The patient was a fireman; always had been healthy until two weeks previous, when he was seized with chill, followed by fever, pain in the side, and cough. The history of the case warranted the assumption that the man had been suffering from a mild attack of malarial fever. His temperature since his admission has been steadily 98° and 99°. The specially interesting feature in his case was the development of pneumonia in the upper portion of the right lung, with but few physical signs which precede consolidation, and was followed by very few physical signs which follow consolidation. Neither rational nor physical history of pneumonia was well developed, which is another illustration of the insidious approach which this disease sometimes makes. This man was recovering, and was again illustrating how patients may contract pneumonia, and recover without developing any marked symptoms; and possibly, perhaps probably, many cases run their entire course unrecognized by the medical attendant. This man was recovering without the development of any *râles râles*, and his lung had been in a condition to produce bronchial breathing. Pneumonia is specially liable to occur without the manifestation of well-defined symptoms denoting either its accession or its resolution, in connection with acute articular rheumatism and delirium tremens. It does occur thus, in connection with other conditions. The inference from the facts is apparent, namely, no physician can be too careful and thorough in the examination of his patients.

ABDOMINAL TUMOR.

This tumor was situated in the abdomen of a man 48 years of age. Family history imperfect. Never vomited blood. Has pain, heaviness, and soreness over the epigastrium. Vomits occasionally. Has more or less of dyspnea, and expectorates considerable white frothy mucus in the morning upon coughing. Appetite is now failing. Examination of urine negative. When the patient sits up all day there will be

some edema of the feet. By some, the edema of the lower extremities which appear, in connection with an anemic condition of the system, and such as is manifested in the latter stages of prolonged diseases, is regarded as being due to a hydremic condition of the blood simply; while others regard the edema as being due to a mechanical cause, that cause being a thrombosis of the veins.

This tumor, like all of its sort, had certain peculiarities which made the question of diagnosis an interesting one. It was situated in the epigastrium, in the position of the great omentum, was non-pulsating, was not adherent to the walls of the abdomen, moved upwards upon inspiration, had an uneven surface, was quite visible, and had diminished somewhat in size since the admission of the patient into the hospital. It was not believed to be carcinomatous, for the reason that carcinomatous tumors do not actually diminish in size. An apparent diminution in size may occur when adhesions are formed between the tumor and such other parts, that when contractions of the adhesions occur the tumor may be drawn away from a distinct recognition by touch. Such a diminution in size may and does occasionally occur. In very rare cases also this class of tumors take on a retrograde action, and diminish in size, but the rarity of such occurrences hardly permits them to be taken into account.

It has existed for five or six months and has not progressed, which is uncommon for a malignant tumor. It was thought that possibly it might be a fecal tumor. The epigastrium is an unusual situation for a fecal tumor, the ordinary situation being in the ascending colon. Fecal tumors are not usually visible, and are ordinarily of greater size than the tumor in the present case. The tumor was not connected with the liver or spleen. It was believed to be due to an inflammatory action which had produced a quantity of plastic material, which had developed adhesion between the various organs and tissues in that region. In the way of treatment the general condition of the patient was looked after, and whatever could be done to improve the general nutrition was being employed.

CHRONIC BRIGHT'S DISEASE.

The features specially noticeable in connection with the case of Mrs. C., æt. 22, married, were as follows: Her family history was good. When a child she had acute articular rheumatism. She now has a valvular lesion at the mitral orifice, which it was believed had existed since the attack of rheumatism. Although the patient gave no history of having suffered in years past from cardiac disease, the conclusion that this valvular lesion had its origin with the attack of rheumatism in childhood was founded upon the general principle, that children with rheumatism almost certainly have some affection of the heart, and that affection may be carried for many years without much pressure. The cardiac lesion may not produce any special symptoms until renal affection begins to manifest itself, when at once the cardiac symptoms may become well marked, and from that time may continue well marked, although the dropsical symptoms may all be removed. Another feature of interest in the case was the occurrence of a spontaneous diuresis. This is a feature which is seen once in about eight or ten cases, and this spontaneous diuresis may mask the real disease and lead to error in diagnosis, unless the symptom is carefully measured and further examination of the case made. Edematous effusions are not liable to be developed when the quantity of urine passed daily exceeds 3 L. In these cases the condition of the kidney ordinarily is one of chronic congestion,

and is secondary to the cardiac disease, and that without any history of cyanosis.

There are three causes for the production of cardiac murmurs: Obstruction in the current of the blood; change in direction of the current of blood; and change in the blood itself.

LARYNGITIS.

Our attention was called to this case as being one in which the affection had succeeded pneumonia. The first manifestations of pneumonia were in the upper lobe of the right lung, and subsequently pneumonia was developed in the left lung. There was some tenderness, as evidenced by giving pain when the larynx was pressed upon its sides or pushed backwards. Aphonia was almost complete, and articulation difficult and tiresome. At the present time the patient complains of pain in the right ear, which goes streaking along the neck from the larynx.

Blisters applied below the larynx have given marked relief with regard to pain. They were applied by means of collodion and cantharides combined, and applied with a brush. It was feared that the case would prove to be one of "tubercular laryngitis." The more modern idea is, that the great majority of cases of laryngitis developed under circumstances, as in connection with phthisis, etc., favoring phthisical changes, are not of tuberculous origin; that the presence of tubercles in the larynx in such cases is the exception and not the rule; that the changes which do take place are of an inflammatory nature. A theory has been advanced that, in cases of laryngeal phthisis, the laryngitis is developed as the result of reflex action, reflected from the lungs; and in support of the theory is mentioned the fact, that the disease commences ordinarily in the side of the larynx corresponding to the lung diseased to the greatest extent. There are several inferences given in its support, but the theory is yet in its infancy. Anodyne applications to the external auditory canal are the most serviceable for the relief, but laudanum is not the preferable one, on account of the irritation which the remedy itself may produce.

PERNICIOUS INTERMITTENT.

The patient had had one or two paroxysms before admission to the hospital. This was nearly all that was learned of his history, for while giving his history he became unconscious. To what his unconsciousness was due, was the first inquiry. There were no special indications of its being uræmic coma, as evinced by condition of pupil, condition of respiration, etc. The pupils in uræmic coma are contracted and equal in size, while in meningeal coma they are dilated, and sometimes unequal in size. Uræmia was excluded. There was no paralysis which would exclude hemiplegic causes. From the absence of symptoms, and the fact that the temperature was raised, and the strengthening fact that the patient had had paroxysms of intermittent fever before coming into the hospital, it was concluded that his case was one of pernicious intermittent fever, and a plan of treatment was adopted in accordance with that view. The man received 50 grs. of the sulphate of quinia within eleven hours, in divided doses hourly. He recovered his consciousness in part, the evening of the same day in which he lapsed into his unconscious state; has had no farther paroxysms, and is recovering slowly but apparently surely. His treatment now embraces a nourishing diet and the administration of quinine and iron.

PNEUMO-HYDRO-THORAX.

This disease was developed in a woman, æt. 30, with good family history, and has always been healthy until her present sickness. She has well-developed signs of phthisis, which, as near as can be ascertained, date their commencement three months ago, when she had pain in side, cough, sickness at stomach, expectorated a whitish matter, and within about one month has been expectorating muco-purulent material. She is now suffering from pneumo-hydro-thorax, and the symptoms which marked its development are worthy of notice. She does not present the appearance of a patient who is very sick. There was no sudden pain, no great lividity of countenance, and no great dyspnea marking the out-set of the attack. Upon physical examination, the ordinary signs of the affection were found well-marked, with tympanitic resonance over the precordial region, and displacement of the heart over to the right side by the pressure of the air in the pleural cavity, in the same manner as it would be by a large fluid accumulation in the left pleural cavity. Succussion was this morning present for the first time. Prognosis unfavorable, and treatment sustaining and palliative. Aspiration may be resorted to when the cavity becomes sufficiently filled with fluid to demand it. The initiatory symptoms are so mild that the case may continue for some months, possibly longer.

APHASIA, WITH LEFT HEMIPLEGIA.

This case was somewhat unique, from the fact that the aphasia was associated with cerebral lesions upon the right side. The thorough and rapid improvement of the patient made it probable that the lesion was a cerebral hemorrhage. Heart normal size, and no murmurs present. The improvement in the hemiplegia followed the ordinary course, and first manifested itself in the lower extremity, and then in the arm. It has been said that when improvement commences first in the arm, it is an unfavorable symptom, and the patients ordinarily succumb to the disease. It is believed, however, that this statement is not always true, for cases occasionally recover when the improvement first manifests itself in the upper extremities. The case was especially noticeable, as an illustration of aphasia with left hemiplegia, which is rare.

Progress of Medical Science.

ON THE PREVENTION OF UTERINE INFLAMMATION.—Dr. E. J. Tilt, of London, believes that most of the uterine inflammation which physicians have to treat is owing to "a bad getting up," or to a bad miscarriage. Among the symptoms denoting "a bad getting up" he mentions general debility, showing itself in various ways, notwithstanding a fair amount of rest, food, and stimulants; an inability to stand or walk a few steps without feeling ready to drop; a sensation of bearing down, and of uneasiness rather than of pain, in the pelvis; the persistence of an abundant vaginal discharge, particularly if it be bloody or muco-purulent, three or four weeks after parturition, when the lochial discharge ought to have ceased. He says: "When such a disturbance of health arises in the midst of other circumstances, or without known cause, it excites alarm and is carefully investigated; but because it has clearly been caused by parturition, the case is often inadequately attended to by the medical practitioner, change of air and tonics being the only things he recommends. The vaginal discharges are not inquired

into; they are set down as leucorrhœa; and he does not even examine to ascertain whether perchance the symptoms may not be caused by the inability of the womb to get back to its proper size. The patient doubtless improves by tonics or the sea-side, but frequently the benefit is not permanent; and either menstruation becomes too painful and too abundant, or there is a bad miscarriage, or a succession of miscarriages, and after several years of this kind of life the patient is only cured when she meets with a practitioner who will take the trouble to ascertain what is really the matter."

The organic lesions of a bad getting up are: *a*, Defective involution of the womb; *b*, Placental ulceration of the uterus; *c*, Contusion of the uterine tissues; *d*, Rupture of the uterine orifices. To the former of these conditions are not only to be traced catarrh of the mucous membrane, and congestion and inflammation of the uterine tissue, but, also, most of the flexions and displacements which the organ undergoes.

Under the head of "How to Prevent a Natural Function from being a Frequent Source of Metritis," he says: "Speaking generally, all improvements in midwifery, such as the judicious shortening of labor by the skillful use of the forceps, will prevent the development of metritis by diminishing traumatism and by husbanding the strength of the womb for the completion of perfect involution.

"Three sets of women," he says further, "require somewhat different advice: 1, Pregnant women who have previously been under treatment for uterine inflammation; 2, Women who are not making good recoveries from parturition; 3, Women who have miscarried."

1. When pregnancy occurs during or soon after surgical treatment of uterine inflammation, it is best to leave it off, with the exception of a vaginal injection once a day if there be a leucorrhœal discharge. Such women should pass the puerperal month in bed, or on the sofa; they should use a vaginal injection, with a solution of acetate of lead, twice a day, so soon as the lochia cease to be red; and, should this continue to be the case for more than eight or ten days after parturition, they should direct the practitioner's attention to the fact. All such women should submit to a speculum examination at the end of the puerperal month, in order to ascertain whether parturition has led to a relapse of cervicitis, because it most frequently does so.

2. When, without presenting signs of more serious puerperal diseases, a patient is recovering badly from labor, the practitioner should ascertain the progress of uterine involution; and, if it be not progressing sufficiently quickly, he should put on a grave face, discountenance getting up, apply a tolerably firm abdominal bandage, and give ergot. Should the vaginal discharge continue red, it is better not to depend on sulphuric acid and astringents, but make a digital vaginal examination. If at the end of the puerperal time a woman remains weak notwithstanding a fair amount of food, of stimulants, and of tonic medicine; if she cannot stand or walk a little without bearing-down sensations and back-pain; if she have still a red or mucopurulent discharge, it would be folly on the part of the obstetrician to permit connection, and to merely recommend change of air, without learning what is really the matter. It is a great point to get a few months' rest from menstrual orgasm for a womb that has recently suffered from inflammation, or shows a leaning thereto, so he encourages nursing, provided the child do not suffer from lack of maternal milk or from its purit.

With regard to abortion, Dr. Tilt says: "It is the

absence of some definite understanding between the profession and the public respecting the rules to be adopted after abortion that renders it a fertile source of metritis. It is well understood by all women placed above the obligation of manual labor that the month following parturition should be one of convalescence, during which the wife should sleep apart from her husband. There is no similar understanding with regard to abortion; women think it right to get about as soon as they can possibly do so, and thus encounter influences which often check the progress of involution." Even when there be no *post-partum* flooding, or signs of severe pelvic inflammation, and in ordinary cases of miscarriage at from three to five months, Dr. Tilt advises that the same course should be followed as after a confinement at term. The object of the practitioner should be to keep the patient in bed or on the sofa for a few weeks; which he can do by talking seriously of miscarriages being worse than confinements, and of the great danger of one abortion being followed by another. In other respects it is safe to treat the case as one of inflammation.

PARENCHYMATOUS INJECTIONS OF IODINE INTO ACUTELY INFLAMED TISSUES.—Although we are familiar with parenchymatous injections of various medicaments in chronic inflammations of certain organs, and in the treatment of some neoplastic and hyperplastic growths, the suggestion of a similar procedure with the tissue of a part acutely inflamed appears at least paradoxical. From an injection of a tissue in a state of phlegmonous inflammation with a substance like iodine, generally accredited with the power of provoking an inflammation, one would naturally expect only an aggravation of the previous condition. Dr. Arthur Menzel, of Trieste, publishes an article in the *Wiener Med. Wochensc.*, of Nov. 8th, 1873, from which the above would seem by no means the necessary consequences.

During the early part of the last year ('73) an exceedingly severe epidemic of diphtheria prevailed at Trieste. The mortality from this disease was very great, and all methods of treatment appeared alike futile. Considering the enormous swelling of the tonsils that attended the affection, it occurred to Dr. Menzel that the caustic applications made to the parts were so often ineffectual from the fact that the disease-engendering material extended deep into the glandular tissue beyond the reach of the superficial applications. He was thus led to try the effect of injecting a solution of iodine into the substance of the inflamed tonsils, in the hope of arresting the local process of disorganization, and at the same time, through absorption of the remedy, to combat the disease throughout the system. In the first case where it was tried the result was surprisingly brilliant. A child, six years old, had suffered from diphtheria for two days. The tonsils were swollen till they met, each presented a patch of membranous exudation, which, being removed, left a corresponding loss of substance. With a Pravaz's syringe five drops of Lugol's solution of iodine were injected into each tonsil. In one day the tonsils had returned to their normal size; the child appeared quite well, and could swallow without difficulty. Only superficial ulcers remained, which healed in a few days.

The remarkable success obtained in this case led to the same treatment being adopted in six others. The injections were usually repeated at intervals of three to four days. Of the seven thus treated, three recovered, two died, and in two the result was unknown, though from the severity of the attack in the two latter cases, a

fatal termination was inferred. The writer admits a ratio of the cured to the fatal cases of but three to four, but claims that, considering the violence of the epidemic, this is not an unfavorable result. The injections were further tried in a case of malignant pustule, and in one of diphtheritic phlegmon of the cheek where the swelling was extreme and tense. In the former the patient died, in spite of injections and repeated incisions, from thrombosis and metastatic deposits in the lungs. The other case recovered.

In concluding, the writer seeks to show that while of his cases only one showed a positively favorable result, the sum-total was not less favorable to this treatment than in cases where other methods were pursued. Of especial importance is the negative result implied in the circumstance that these injections, in no case, caused an aggravation of the existing condition, or led to gangrene of the tissue. He would thence infer that, very possibly in milder forms of inflammation—not diphtheritic—as, for instance, erysipelas, or in ordinary phlegmon, a more favorable result might be expected from such injections, either of iodine or of carbolic acid, quinine, bromide of potassium, or ergotine, etc. The impunity with which his injections with Lugol's solution were made justify further trial in this direction.

THE TREATMENT OF SYCOSIS AT THE INFIRMARY FOR DISEASES OF THE SKIN IN CANNSTADT.—The beard is first cropped as closely as possible with shears, and the scabs are then removed by poultices of linseed-meal or bread and milk, which usually requires from six to eight hours. The part is then anointed with a salve consisting of one part of green soap to two parts of common tar, three times a day for two days, for the purpose of loosening the hairs, after which the latter are removed with ciliary forceps. Upon the epilated surface acetic acid is now applied with a brush, which causes severe pain and swelling, together with a secretion of serous fluid from the hair-follicles. In twenty-four hours the surface is covered with a dry crust, which falls off in from three to four days. The syccosis is then healed, and only requires observation of the epilated places for three or four weeks to guard against relapses. During this time a paste of lac sulphur and alcohol, with enough mucilage to prevent drying, is applied, and at the end a slightly astringent wash, consisting of benzoic acid, alcohol, and spirits of camphor, by means of which the redness of the skin is removed. The hairs are soon regenerated, this course of treatment not having prejudiced their growth. The treatment is assisted by baths and gentle laxatives.

Salves and fatty preparations, it is thought, are not suited to the treatment of syccosis. The salves of white precipitate and tar, often recommended, only serve to render the disease more obstinate.—*Blätter f. Heilwissenschaft.*—*Memorabilien*, xviii., 9.

MAY PULMONARY PHTHISIS BE DEPENDENT ON PRIMARY AFFECTIONS IN THE LARYNX?—To determine this question, Sommerbrodt, of Breslau, instituted a series of experiments upon rabbits. A hot wire was passed through the upper part of the trachea, and there allowed to remain, setting up a chronic inflammation which terminated fatally in from four to ten weeks. During this period the following appearances were observed: In from eight to ten days cheesy deposits were found in the submucous tissue, varying in size from a pea to a hazelnut. The membrane ulcerated and the cartilage was exposed. The inflammation descended more or less rapidly to the finest bronchial tubes, thence to the peri-bronchial tissue, and to the parenchyma proper of the lungs. The condition in the lat-

ter situation was characterized by isolated brownish or yellowish red thickenings of the tissue, between which were emphysematous spots. The extension of the process could be traced from the vicinity of the bronchia on to the septa of the alveoli, which were thickened, with infiltration of lymph-cells, together with a desquamation of the alveolar epithelium. It thus corresponded very nearly to the peri-bronchitis purulenta and desquamative pneumonia of Buhl. The writer, embracing Buhl's doctrine regarding the deleterious nature of this process, concludes from his experiments that the chronic inflammatory irritation of the trachea leads to peri-bronchitis purulenta, and in its further course to phthisis pulmonum. That the cheesy deposits in the trachea are not to be regarded as the source of the lung affection, was evident from farther experiments, where caseous abscesses were produced in other animals in various parts of the body, but in these cases only lobar, croupous, and caseous pneumonia were found, without the characteristic affection of the bronchial tissue. When the wire was passed through the trachea of dogs, there was developed only inflammation of the laryngeal and tracheal mucous membrane, the bronchi and lungs remaining unaffected.—*Archiv für experiment. Pathol. u. Pharm.*, i., 1873. *Ibid.*, 44.—*Allg. Med. Central-Z.*, 83.

CARBON AS AN ANTIDOTE TO PHOSPHORUS.—Eulenberg and Vohl have demonstrated by experiments that carbon fixes and absorbs phosphorus. If phosphorated oil be filtered through dried animal carbon, excluded from the air, the oil will pass through the filter, but not a particle of the phosphorus. Experiments with guinea-pigs confirm the efficacy of this method by protecting them from phosphorus-poisoning.

The salts of copper have already been recognized as useful in this variety of poisoning, as they are reduced and precipitated by the phosphorus. The fragments of the latter are thus prevented from acting on the organism.

These authors, therefore, suggest that sulphate of copper be first given as an emetic, and, after vomiting has taken place, that the carbon be given alone. They also propose the use of carbon as a prophylactic measure. Artisans exposed to the vapors of phosphorus should wear a respiratory apparatus filled with recently prepared animal carbon.—(*Ann. di Chim. del Polli*, Sept., 1873, and *Lo Sperimentale*, No. 11, 1873.)

SECOND MENSTRUATION FROM THE MAMMÆ AT FIFTY YEARS OF AGE.—Tuffard reports the somewhat curious case of a lymphatic and anæmic woman who menstruated regularly until she was 50 years old, and had had two children. She suffered from granulations of the neck of the uterus. After the cessation of the catamenia the mammae became turgid and painful every month, and there escaped from the nipples a fluid which was serous at first, and then became sanguinolent and lasted eight days.—*Union Méd.* and *Lo Sperimentale*, Oct., 1873.

ARSENIC-POISONING FROM A GREEN CARPET.—At the July meeting of the Swedish Medical Society, Dr. Kjellberg reported the case of a young man who presented the premonitory symptoms of arsenic-poisoning. He had suffered in a similar way a year previously, but was entirely cured by travelling. The attention of the physician was directed to the peculiar color of the carpet in the patient's room. The color was grayish green. He became suspicious, and had a piece examined chemically, and it was found to contain a considerable quantity of arsenious acid. A new carpet was substituted and the patient recovered completely without further treatment.—*Hygeia, Stockholm*, Oct., 1873.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, February 2, 1874.

HOSPITAL APPOINTMENTS.

EVERY time that a new appointment is made in one of our great city hospitals, the system regulating such appointments deserves fresh consideration. For in this, as in much else that pertains to the management of the medical world, we are so notoriously behind the times and below the standard existing in other civilized countries, that the nature of the principles on which the system depends cannot be too carefully investigated. It is a pure pocket-borough system, just such as in England controlled political appointments previous to the triumph of political reform. The merits of candidates are not canvassed before any competent tribunal, nor is any opportunity offered for a fair test of such merits by open competition or trial of skill. The appointments go by favor, depend upon purely personal influence, and the influence of men who professionally are unable to decide, by their own judgment, on the relative fitness of rival claimants. Political position, even high political character and integrity, offer no guarantee of ability to estimate the qualifications required for technical medical duties. Yet at present no other guarantee exists, and even this, as every one knows, is often wanting. Hospital appointments are exclusively in the hands of hospital commissioners, whose choice, unguided by medical knowledge or professional sympathies, can depend on nothing but political friendships, obligations, and alliances. The recommendation of an alderman counts for more than that of a medical society, or of the entire medical faculty of a community, and the request of a mayor or a governor is sufficient to turn the scale. Moreover, in order to leave the matter as much as possible to the control of such influences, care is taken to avoid the publicity that might bring others into play. The occurrence of a hospital vacancy, that should be a public

event in the medical world, formally announced in order to summon all worthy candidates to a strenuous trial of skill, is, on the contrary, kept as secret as possible. It is suspected, whispered abroad, and secret signals beckon privately favored ones to the best places, so that before the apparent competition begins the affair is already decided.

Now this system is as radically absurd, when the successful candidate is really worthy of the place, as when his abilities are markedly inferior to those of rivals forced to retire from the field.

A great opportunity is thus lost for the development of talent, the demonstration of intellectual force, the encouragement of honorable ambitions, the stimulus to exertion in the higher departments of medical work. Without such stimulus such exertions must flag and fail; ambition knows but one outlet—making a successful practice—and all the energies of all the members of the profession are bent in this direction. To this cause is largely to be attributed the comparative sterility amongst us of original research, the indifference to pure science which seems to offer no rewards either in money or fame. Here and there a solitary enthusiast pursues his theme, regardless of public opinion or popular applause; but he is the exception. The intellectual life of the great cities of England, France, and Germany is unknown among us, for there is no competition, no prizes to compete for, no judges to award the prize. Hence the intellectual mediocrity that, however we may blind our eyes to it, contrasts so painfully with our boasted practical efficiency.

The remedy is only to be found where other countries have found it, in the substitution of competitive trials of skill before a jury of physicians, for the exertion of mere personal influence upon a political committee.

A hospital position should be of immense value as a means not only of relieving suffering, but of adding to personal experience, of pursuing original researches, of carrying on the most important part of medical education. Hence it should only be accorded to the candidate who has given proof of experience, learning, skill in diagnosis, and ability to teach. At the competitive examinations in Europe, for whose preparation years of study are not deemed superfluous, candidates diagnose difficult cases, give clinical lectures by the bedside, and afterwards write theses on a subject drawn by lot from a list. According to the extent of information, penetration of judgment, medical sagacity, and ability to write and lecture that may be displayed by each, are their rival claims estimated by the medical jury whose recommendation decides the decision of the political power upon whose choice the appointment only nominally depends.

This system has its defects and may be immoderately abused, but it has at least the merit of confining competition to a certain range of capacities, of excluding marked incapacities, of rewarding honest work, and of

affording a brisk stimulus to work even among many who never are rewarded. It is the only fair and democratic method. With us it already dominates the appointments of sanitary inspectors and of hospital internes; it remains to be extended to the nomination of hospital physicians.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR.

It may not be uninteresting to our readers to be informed concerning the distribution of the first part of the Medical and Surgical History of the War. The following is an extract from the annual report of the Surgeon-General for 1873, and speaks for itself:

Sent to Congressional Committees as specimens.....	12
“ Senators.....	1,000
“ Representatives.....	2,000
“ Library of Congress.....	50
Damaged and imperfect copies.....	70
To be issued by Surgeon-General's office.....	1,868
Total number of copies printed.....	5,000

It can be seen from this statement what a small proportion of these volumes, so highly prized by the profession, have fallen to their share. Generally speaking, publications upon medical subjects by legislative bodies are very properly viewed by the profession as a useless expenditure of public money for the sake of creating political capital and extending the area of official patronage, a shining example of which was the voluminous, useless, and abominable report of the Columbian Hospital for Women, at Washington. But with the Medical and Surgical History of the Rebellion the interest manifested throughout the whole profession amounted to an enthusiasm worthy of a national work in the hands of the first medical investigators of the country. No work, in fact, published in America has been more eagerly sought on account of its intrinsic value than this one, and every contributor at least rightly believed that he had a claim to a copy, and this belief was strengthened into a prospective certainty when it became known that the distribution was to be intrusted to the Surgeon-General. In the figures before us we have the best explanation why the supply has been so limited as to leave the vast majority of those entitled to the work without it.

We should like to know what has become of the three thousand copies appropriated by the legislators, what were the measures adopted to secure their faithful distribution to such of their constituents as would value the books, and what proportion drifted into the hands of those who helped to make the work what it is by their valuable experiences upon the battlefield and in the general hospitals.

THE ARMY RANK BILL.

The army rank bill has been presented to Congress, and has been referred to the House Military Committee.

As an offset to its favorable consideration, we hear of a proposition to reduce the army to twenty thousand men, and the staff in proportion. This is certainly a very inauspicious beginning, and proves the existence in essence, if not in fact, of an indifference to the claims which any corps may have for extra consideration and reward. We hope, however, that our suspicions are unfounded.

It is well to know, in connection with matters in which the profession has no little concern, that the Appropriation Committee have recommended the reduction of the usual amount of ten thousand dollars for the Army Medical Museum and Library, to three thousand. If this is done, the Museum can just exist, and no more, and the collections for the Library must stop. The gentleman who proposes this reduction certainly takes upon himself a grave responsibility, and he owes it to his conscience to give a satisfactory reason therefor to a profession who are alone able to judge of the necessity for keeping both these institutions in a healthful state of progression.

Reviews and Notices of Books.

THE TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION. Vol. xxiv. Philadelphia, 1873.

It is certainly not an honor to our profession that the above volume should go forth to the world as an exponent of the present *status* of medical knowledge in America. It contains but little that is above mediocrity, and, in opposition to the opinion of the President, we claim that it does *not* represent the views of the majority of the profession, and is unworthy of the talent on our side of the water. Much of the short time devoted to the general meeting was wasted in useless discussion, and the meetings of the sections were characterized by a lack of interest among the members in the presentation of scientific papers, as the result of which followed the organization of so-called “practical experience meetings.” It is refreshing to observe the opposition which was made by several members against publishing much of the trashy material which was here brought forward.

The papers which have been published in *extenso* are: On the *Education of the Medical Senses*, from the able pen of Dr. Edward Seguin, in which the author advocates greater *subjective* training of the senses than has hitherto been customary with students during their curriculum; Dr. Thomas M. Drysdale, *On the Granular Cell in Ovarian Fluid*, which is also mentioned and portrayed in Dr. Atlee's recent work. Notwithstanding the endorsement of this high authority, we believe that the author has not, as yet, sufficiently substantiated his claim among microscopists. Dr. C. H. Lothrop, before the section on surgery and anatomy, read a paper on the *Treatment of Bunions*, in which he recommends the gradual persuasion of the toe to its normal position by the use of strips of adhesive plaster placed upon and around the heel, the free extremities of which are attached, by means of a rubber band, to a cot placed upon the toe. The *Report on the Climatology and Epidemics of Pennsylvania* is very incomplete, and the *Statistics of Regular Medical Associations and Hospitals of the United States*, and the *Report on American*

Neurology, occupy one-fourth of the volume, and might either have been left out entirely or materially condensed.

The President delivered a lengthy and able address, but entirely ignored the fact that the Association is, year by year, losing more ground, and offered no suggestions by which the latent forces of our medical talent might again be rallied. The reasons for the misrepresentation of the profession in this Association have been repeatedly set forth in the columns of this journal, and we fear that unless there is a thorough reorganization, and a removal of "the powers behind the throne," it will, within a few years, have been a thing of the past.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 22, 1873.

THE PRESIDENT, DR. ELLSWORTH ELIOT, in the Chair.

NEW MEMBERS.

THE following persons, recommended by the Comitia Minora, were granted certificates of membership:—HORATIO BRIDGE, 22 East 41st st., a graduate in medicine at Harvard College, Cambridge, Mass., in 1871; THOMAS T. SABINE, 46 West 23d st., a graduate in medicine at the College of Physicians and Surgeons, Medical Department of Columbia College, in 1864; BENJAMIN L. SCHARLAN, 15 Beach st., a graduate in medicine at the University of Berlin, Germany, in 1864; LUCIAN C. WARREN, 749 Sixth av., a graduate in medicine at the Medical Department of the University of the city of New York, in 1867; COERT DUBOIS, Woman's Hospital, a graduate in medicine at the College of Physicians and Surgeons, Medical Department of Columbia College, in 1872; AUGUSTUS VIELE, 579 Lexington Av., a graduate in medicine at the College of Physicians and Surgeons, at Fairfield, N. Y., in 1837; ALEXANDER C. GRAHAM, 159 East 46th st., a graduate in medicine at the Bellevue Hospital Medical College, in 1869; ANDREW R. ROBINSON, a graduate in medicine at the Bellevue Hospital Medical College, in 1868; WILLIAM F. MITTENDORF, 110 East 27th st., a graduate in medicine at the College of Physicians and Surgeons, Medical Department of Columbia College, in 1873; EDWARD G. LORING, 151 Lexington Av., a graduate in medicine at Harvard College, Cambridge, Mass., in 1864.

DECEASED MEMBERS.

THE PRESIDENT announced the death of the following members of the Society:

ALFRED UNDERHILL, M.D., a member since January 24, 1834, who died on Sunday, Dec. 7th, in the sixty-fifth year of his age. Deceased was born and always resided in New York. He was a graduate in Arts of Columbia College, and in Medicine, of the College of Physicians and Surgeons. He began practice in 1830, and had held the offices of President of the Society, Vice-President of the Academy of Medicine, etc.; MERRILL W. WILLIAMS, M.D., member of the Society since Feb. 15th, 1830, who died in the seventy-third year of his age; WILLIAM C. ROBERTS, M.D., member since July 4th, 1832, who died Dec. 9th, in the sixty-fourth year of his age. Dr. Roberts was born in London, England, and emigrated to this country when fourteen years old. He studied and began the practice

of medicine under the supervision of Dr. Valentine Mott. Dr. Roberts was a graduate of the College of Physicians and Surgeons. At one time he edited a medical periodical known as *The Analyst*, and at the time of his death was surgeon to the Central Park Police, and Vice-President of the New York Academy of Medicine; J. E. STILLWELL, M.D., member since May 26th, 1838, who died Nov. 26th, aged sixty years; JONAS P. LOINES, M.D., member since Feb. 1871, who died Dec. 15; PETER VAN BUREN, M.D., member since Jan. 9, 1871, who died Dec. 5th, aged seventy-one years.

DR. CHEESMAN presented to the Society a memorial of the late Dr. Roberts, which was accepted and placed on file.

THE LATE DR. M. W. WILLIAMS.

DR. VAN KLEEK likewise offered resolutions regarding the death of Dr. M. W. Williams, as follows:

Resolved, That this Society has heard with deep regret of the sudden removal by death of Dr. Merrill W. Williams, for many years a member in good standing, and who by his faithfulness and devotion to his profession, his worth and probity as a man, his zeal and earnestness as a Christian, has adorned a well-ordered life and labors, from which he has gone to a reward and a crown, with the commendation of "Well done, good and faithful servant, enter into thy rest."

THE LATE DR. JONAS P. LOINES.

DR. O'SULLIVAN offered the following preamble and resolutions regarding the decease of Dr. Loines:

Whereas, The Medical Society of the County of New York has learned with deep regret of the death of their esteemed fellow-member, Jonas P. Loines, M.D., and while bowing with due submission to the will of the inscrutable and divine Providence, we deem it a duty to place on record a tribute of respect to the memory of our deceased brother, and our appreciation of the services he has rendered to the medical profession of this city by his arduous and unassuming labors as Vaccine Physician to the Eastern Dispensary for upwards of twenty-two years:

Resolved, That in his eminent abilities, untiring energy, and amiable character, we recognize all the qualities that go to constitute the honorable physician: a mind alert and observant; a keenly discriminating judgment; diligence in study, and a heart sympathizing with all the ills of human life.

Resolved, That we tender to the family our heartfelt sympathy in their bereavement, and that a duly authenticated copy of these resolutions be transmitted to them and recorded in full on the minutes.

THE LATE DR. PETER VAN BUREN.

THE SECRETARY read for Dr. B. F. Barker, who was unable to be present, the following resolutions relative to the late Dr. Van Buren:

Resolved, That this Society has heard with deep regret of the death of Dr. Peter Van Buren, one of its most respected members, and formerly Vice-President of the Medical Society of the State of New York.

Resolved, That while the professional ability and attainments of the late Dr. Van Buren commanded the respect and secured the confidence of the public, his sterling integrity and Christian character, his devotion to the duties of his profession, and his regard for its dignity and honor during his long life, will ever remain as an example worthy of imitation.

Resolved, That this Society tender to the family of the deceased its deep sympathy and sincere condolence with their bereavement, and that the Secretary be directed to forward to the family a copy of these resolu-

tions; and also that a copy be furnished to each of the medical journals of this city for publication.

Adopted.

REPORTS OF COMMITTEES.

A report by Dr. Goodwillie, of the Committee on Meteorology, was followed by

THE PAPER OF THE EVENING,

by DR. MARY PUTNAM JACOBI, the subject being "The Pathology of Infantile Paralysis."

HONORARY MEMBER.

The President announced that at the last meeting relative to the Comitia Minora the name of DR. ARTHUR ERNEST SANSON, of London, was proposed for Honorary Membership, and it was voted to recommend his election at the next meeting of the Society.

MEMORIAL OF THE AMERICAN MEDICAL ASSOCIATION.

The memorial of the American Medical Association relative to the rank of the Medical Corps of the United States Army was presented by the President, who said that the *Academy of Medicine* had already appointed a committee to draft suitable resolutions expressive of their sympathy with the medical officers of the service in this movement.

On motion of Dr. J. C. Peters, a committee, consisting of Drs. H. B. Sands, A. C. Post, and I. E. Taylor was appointed by the President to consider the memorial and report at the next meeting of the Society.

CONTRIBUTION TO THE LIBRARY.

DR. JACOBI announced that he had received from Germany a number of pamphlets which had been donated to this Society. On motion they were presented to the Medical Library and Journal Association.

SUBJECT OF NEXT PAPER.

The President announced that DR. MOREAU MORRIS would present to the Society, at its meeting in January, a report of the Committee on Hygiene, of which he is Chairman, on the subject of Drainage, which would be the paper of the evening.

DR. O'SULLIVAN inquired what action, if any, had been taken with regard to the publication of the proceedings of the State Society, and especially what disposition had been made of papers submitted to the Committee on Publication. He had read a paper in 1867, which was referred to the Committee on Publication, but which had never as yet been published.

The President referred him to the Secretary of the State Society for information.

The meeting then adjourned.

NEW YORK MEDICO-LEGAL SOCIETY.

Stated Meeting, Dec. 26, 1873.

CLARK BELL, Esq., President, in the Chair.

ARMY STAFF RANK.

DR. J. C. PETERS moved the appointment of a committee of seven to take into consideration the subject of a memorial of the American Medical Association with regard to the rank of the medical corps of the U. S. Army, based upon the annual report of the Surgeon-General. The committee consisted of the Hon. C. P. Daly; Prof. L. A. Sayre, M.D.; Geo. H. Yeaman, Esq.; E. W. Stoughton, Esq.; Geo. Tichnor Curtis, Esq.; Dr. J. C. Peters, and Prof. W. A. Hammond, M.D.

MEDICAL JURISPRUDENCE OF THE STOKES CASE.

The Society then listened to the paper of the evening, by EUGÈNE PEUGNET, M.D., entitled *The Medical Jurisprudence of the Stokes Case*, of which the following is an abstract:

"*Ex errore citius emergit veritas quam ex confusione.*"

The medical evidence in the repeated trials of this *cause célèbre* has given rise to so much comment, and there has been such a diversity of opinion in regard to it, that a critical analysis of its medical jurisprudence, as presented both by the prosecution and the defence, may render much that is apparently obscure clear, also further the interests of science, and in the future those of a proper administration of justice. It is evident that the juries in the first and third trials were not directly influenced by the medical testimony; it is even doubtful if they took the slightest notice of it. But, nevertheless, it may have had that indirect influence, so frequently made use of by our most successful criminal lawyers, of diverting the attention of the jury from the merits of the case. In this instance it may only have served as a wedge to cast a doubt in the minds of the jurors; for a wedge once well driven in would split the stoutest oak: *Cuneus cuneum trudit*. If the medical evidence failed to have any weight in the trials of this case, it was entirely due to the want of a proper appreciation of its strength on the part of the prosecution. This can only be explained either by a complete ignorance of the first principles of medical jurisprudence, or else by a most profound contempt for it.

Ever since the regular introduction of medical evidence in criminal trials, *coaching* has assumed a prominent position in them. In Europe—especially in France and Germany—this coaching, or medical prompting, is never neglected, and through it the science of medical jurisprudence has there assumed a proud and enviable distinction. But in this country the neglect of it—or rather the want of a proper appreciation of its merits—has served to bring it as well as medical expertise into contempt. Our criminal annals overflow with such cases. Why, just think of it! We have had in the last few years, not even a decade, the Schœppe-Steinecke, Wharton-Ketchum, Wharton-Vanness, Heggi-Seigfried, Stokes-Fisk, and the remarkable *de lunaticis-inquirendo* Train case, and sequence. In the first of these the Medico-legal Society of the City of New York, whilst yet in its infancy, achieved an imperishable renown by obtaining a new trial for the accused, and preventing, in the words of the learned justice who presided at the last trial, A LEGAL MURDER.

Any of these cases would have been suitable for his theme, but the Stokes-Fisk case probably affords the best and most varied illustration of it. Before entering into a discussion of the points involved in this instance, the doctor gave a concise medical history of the case, extracted from the transcript of the stenographer's notes; then entered into the discussion of shock in its various phases, the physiological and toxic actions of morphia, and the nature of penetrating gunshot wounds of the abdomen.

This case, either for the prosecution or for the defence, thus presented two points for consideration: 1, as to the cause of death; and 2, as to the bearing the two wounds had on the relative positions of the aggressor and his victim at the time of the homicide. The prosecution proved by its own witnesses that this wound was not necessarily fatal, and that the victim died of opium-poisoning. The wound in the left arm, with the holes in the left side of the cloak and the

one in the back of it, taken in connection with the victim's *ante-mortem* statement and with the prisoner's own evidence as to their relative positions, conclusively demonstrated that Fisk could not have held his hands as sworn to by the prisoner, but that the former's left hand was resting on the south-side rail of the staircase, and that as he turned towards the door on receipt of the first wound in the abdomen, the second ball struck the left arm just above the crease of the elbow. *This was the pivot upon which the case for the prosecution rested through three trials, yet they failed to see it.* To this irrefragable evidence, coming as it were from the grave, they preferred the more than doubtful testimony of Tommy Hart, which was effectually contradicted by the direction of the wound in the abdomen.

The only conclusions to arrive at were that: 1, the shooting was not done in self-defence, but with meditation; and 2, the wound in the abdomen was not necessarily fatal, and the deceased died of poisoning by morphine. These thus proved an attempt to commit murder in the first degree.

The above are *post-hoc* conclusions on a *res adjudicata*, and therefore of but little practical value as applied to the merits of this case. Moreover, it would indeed be an instance of a *mons parturiciens*, were not all the points in the whole case pregnant with importance as regards the urgency of a change—

I. In the manner of conducting ante- and post-mortem inquests by the coroners; and

II. A modification in the method of introducing expert testimony into criminal trials.

For all the cases referred to in the opening afford a striking illustration of similar points.

During the discussion which followed the reading of the paper.

Dr. McCREADY referred to the formula after which Magendie's solution is made. The old formula is different from the present. It is not official. It has been the custom, after the Germans, of weighing liquids. But pharmacists, in compounding prescriptions, should follow the customs of the country, and not those of a foreign empire.

He referred to the fact that while poisons were invincible in their actions, the peculiarities of the human system are very variable. There are always a few leading symptoms which determine our judgment. There are an immense variety of minor symptoms. This peculiarity of poisons may go far to solve the Stokes case. A case is related in Taylor where an individual swallowed a wine-glassful of acid, but its effects were not observable until the expiration of seven hours. So in the case of Stokes, the opium might not have showed itself until after a time.

Dr. SAYRE agreed entirely with the idea that large doses of narcotic poison may be taken without the usual symptoms being manifested. The dose may be so large as to paralyze the stomach, so that absorption may cease for the time, while after a while its effects will be produced immediately.

In regard to Fisk's case, Dr. Sayre gave a history of him as he saw him: "I have had no theory in regard to the matter, except the practical fact that I saw the patient. It was about 9.30 P.M. He was then lying on his back; the arm bandaged. He was very pale. There appeared to be a paralysis of the entire capillary circulation. The pulse was nearly normal. He was perfectly composed, except that he complained of the pain. He described it as a "green-apple belly-ache." He was rather in a jocular mood. I thought like telling him that he had such a pain that I thought he would not digest freely. I came very near making such a re-

ply. I examined him with a great deal of care, and found that the wound had passed in the right side below the nipple. You could see the track of the wound between the masses of fat. One of the young men of the hotel said he would show me the position of the parties when they were engaged in firing. The position occupied by Fisk would necessarily bring the ball out at the opposite hip. I could not find where the ball had gone through. That was the extent of my treatment, and when I saw him again at 12 o'clock, he was under the influence of opium, as I think. It was myself who drew the attention of the physicians to this. I made them count up and measure the quantity given. It was then that Dr. White and myself went back into the room and saw the man, and I then ascertained that the pupils contracted under the influence of light and were normally dilated; his respiration was 22 or 23; it was not the respiration of opium, and the pupils were not permanently contracted. From these facts, I did not think he was narcotized. When I went into the room first, I thought he had been narcotized. From that time opium was stopped, and from the fact that he got up in the night for water, and answered questions, I infer that he was not narcotized. The pallor of his surface and the lack of capillary circulation made me at the time think that there was some injury of the great sympathetic nerve.

Dr. CHARLES A. LEALE stated that at the trial of Stokes he said that he did not consider the wound that Fisk received a necessarily fatal one, as others had testified, and based that conclusion from his own personal experience both in army and civil practice. He then cited the histories of three illustrative cases, where his patients are now living, over seven years after having been wounded. The first was that of a lieutenant, whose abdomen was perforated by a minié-ball, and in consequence had an artificial anus at entrance and exit of ball. In this instance it was twenty-seven days before the first passage of feces by the anus followed. Extensive splanchnitis of the omentum and coverings followed, sloughs being removed daily for some time. To prove that at least two perforations existed, Dr. Leale injected water through the anterior opening, and as it did not pass through to the posterior opening, and as the discharges from one were much more yellow and liquid than those from the posterior wound, he concluded that the anterior wound communicated with a wounded knuckle of the small intestine, and that the posterior wound opened into the colon. Dr. Leale subsequently closed both by operations, and when he heard from his patient, five years afterwards, was informed that as long as he did not become constive he was in good condition; otherwise pain occurred while feces passed the constrictions of the intestines.

Dr. Leale's second case was that of a major, who was shot through the upper part of the ilium and across the lower abdominal region, the ball passing out from corresponding point of other ilium. He was wounded while leaning forward on horseback, encouraging his men on to action. In this instance paralysis of all the body below the waist followed, and the feces and urine were passed involuntarily. Dr. Leale removed several pieces of fractured bones, which were sources of irritation. Five years afterwards he was still under his care, and now, eight years after being wounded, can walk without a cane, and is an active brewer in the northern part of this State.

Dr. Leale's third case of recovery, he stated, was as near like that of Fisk's wound as would probably occur. In this instance, John Grindall, while going upstairs, was shot by a man three feet in front of him, by a ball from a Smith & Wesson pistol. The ball en-

tered near the right and upper border of the umbilical region, passing inwards and downwards, not making its exit. The patient was made to assume the same relative position as when shot, when the probe pointed to a part of the back, where a hard substance was supposed to be felt. Dr. Leale made an incision about one inch in depth, and withdrew the ball from its place of lodgment beneath the lumbar aponeurosis. For two weeks the man was kept partially under the influence of opium, and without a movement from the bowels. Seven years afterwards he saw him, and found that he still suffered from strictures and adhesions of the intestines. As these patients are all now alive, and having known of instances where, after a long period of time, bullets which had penetrated the abdomen had been passed by the anus, also instances where pieces of shell, handles of knives, bullets, etc., had remained in the cavities of the body for years, he became convinced, and when asked, "Do you consider the wound that Fisk received a necessarily fatal one?" he stated, "Mr. President, with comparative ease, I can answer, No."

DR. SAYRE. One of the reasons I gave for my opinion in regard to Fisk's necessarily fatal accident, was the character of the wound, and the fact that the ball did not pass through and through. A wound in the abdomen may not necessarily be fatal. But when you say that he was wounded precisely like Fisk, how do you know? The only way to decide this whole question is to place Stokes in the same position that Fisk was when he received the ball, have him wounded in precisely the same way, and let him get well or die without the aid of a doctor. That will prove it without a doubt.

After a few remarks by Dr. Peugnet, the meeting adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Dec. 10, 1873.

DR. E. L. KEYES, VICE-PRESIDENT, in the Chair.

DR. JOHN C. PETERS announced the death of Dr. W. C. Roberts, the first Secretary of this Society. After alluding to the valuable services of the deceased, he moved the appointment by the chair of a committee to draw up suitable resolutions. The chair appointed Dr. J. C. Peters and F. V. White as such committee.

WAXY LIVER AND PLASTIC PERITONITIS.

DR. E. PEUGNET presented a specimen of waxy liver and plastic peritonitis, in which all the abdominal organs, with the exception of the kidneys and spleen, were firmly agglutinated together.

A man, 30 years of age, by profession a chief cook, had always enjoyed good health until about the 15th of August, 1873, when he observed that his abdomen was becoming distended, and that towards evening there was an unusual sensation of heat in it. On the 1st of November he came under the doctor's care. At that time he was somewhat emaciated, the skin dry, pulse 98, tongue normal, temperature also; the secretion of urine rather scanty, but presented nothing otherwise abnormal; bowels regular, and some inappetency. The abdomen was very much distended, and superficial veins prominent. On percussion there was marked dullness over the entire abdominal region; the liver did not appear to extend upwards; there was no dullness above the sixth rib. Inquiry into the previous history yielded negative results. He had been a moderate drinker, had had chancreoids, but no traces of syphilis;

never had intermittent fever. A drastic cathartic was then given to him. On the 3d, his general condition was about the same; there was a marked wave-like motion caused by bilateral percussion, but the universal dullness still persisted. On the 12th of November he rode out in a carriage; was taken the next day with a chill, November 14. Pulse 112, temperature $102\frac{1}{2}$, tongue bluish red, with raised papillae. Slight dullness on percussion of right side, extending to inferior angle of scapula, respiratory murmur obscure in lower lobe, with moist and dry râles in upper half; left side normal. 20th. Condition about same, asthenia more marked, considerable dyspnoea, less turgidity of the abdomen. November 22. Dyspnoea more marked. Temperature continues at $102\frac{1}{2}$; dullness over right lung more extensive; râles still present, with inability to lie on back or left side; respiration puerile on left side. November 30th. Pulse 130, temperature still persistent at $102\frac{1}{2}$; dyspnoea intense. Introduced trochar in abdomen, midway between umbilicus and symphysis, and drew off three quarts of a reddish serum; a director had to be introduced into the canula to push back an obstruction to the flow. On microscopical examination of the fluid numerous blood-corpuscles were found, but no cecchinioli or any cell-structure. December 1st. Dyspnoea not as intense, pulse 112, temperature $102\frac{1}{2}$; a distinct tumor was felt in left hypochondrium, extending into epigastrium. On percussion, there was slight resonance over this tumor, but more on left side over descending colon. The dullness on right side in an oblique line from cartilage ninth rib on left side to crest of ilium persistent, which was supposed to be due to a cyst. December 3d. Patient gradually sinking; effusion in right pleura more extensive; none on left side; last time seen alive; he died on the 7th instant.

The autopsy was made seventeen hours after death. Rigor mortis well marked, body slightly emaciated. On opening the thorax a serous effusion was observed in both pleural cavities; the right contained about three pints, the left five pints. There was an old adhesion, with a cicatrix, at apex of left lung; the upper and middle lobes of right lung were slightly emaciated. The pericardium contained half an ounce of serum, and the heart rather smaller than usual, but normal. The abdomen was somewhat distended, and the anterior surface of the omentum was firmly adherent to the anterior parietal reflection of the peritoneum, its cavity distended and forming a distinct cyst from the left hypochondrium obliquely downwards towards the right iliac region. The greater cavity of the peritoneum contained three quarts of reddish serum, similar to that which had been drawn in tapping. The cavity of the omentum contained two quarts. All the viscera were so firmly bound together that it was found necessary to remove them all *en masse* with the diaphragm; with the exception of the spleen the entire mass weighed 18 pounds. On further examination the liver was found to be waxy and enlarged; there were some recent adhesions between the diaphragm and liver. The tumor *delecta* in the epigastrium and left hypochondriac regions proved to be a large collection of omental fat, and the resonance was due to its situation over the transverse colon. The kidneys were somewhat enlarged, but normal. The points of interest in this case were: 1. The entire absence of previous history of any cachexia whatsoever. 2. No account of any previous peritonitis; and, 3. That these intimate adhesions had never led to any intestinal obstruction. It is possible that auscultatory percussion might have revealed the exact size of the liver, and it is to be regretted that it was not made use of.

DR. KNAPP exhibited a patient with epithelioma of

lower lid, upon whom he intended to perform a plastic operation.

INTUSSUSCEPTION.

DR. LEWIS SMITH exhibited a portion of the intestine of an infant who died at the Nursery and Child's Hospital rather suddenly after a trifling illness of but thirty hours. No diagnosis was made, the only noticeable symptom being an attack of vomiting. At the autopsy all the organs of the body were found healthy, with the exception of a portion of the small intestine fourteen inches above ileo-cæcal valve, which was presented, and which was the seat of an intussusception. The incarcerated portion was three inches in length, and presented a deep-red appearance, evidently the result of intense congestion. It was evident that the intussusception existed some hours before death, and proved the case to be an interesting one occurring in so young an infant.

Correspondence.

BRONCHIAL CASTS.

THE following letter, sent to Prof. Flint, furnishes some additional points to the specimen of bronchial casts presented by him at the recent meeting of the Pathological Society:

BERLIN, Dec. 9, 1873.

DEAR SIR—When I wrote you last the information I furnished was rather premature to give you a fair chance of understanding the case. I think the letter was dated on the 18th, and up to that time everything was correctly stated; but the next day another terrible change for me, in the symptoms, began. I was so pleased after the expectation of the casts that I could inflate the lung so much better, that I was, I suppose, practising the new function too much, and either from the irritation of the air or some other cause, a most violent pneumonia set in in the right lung. After such frightful loss of blood I could not believe an inflam-

mation would take place, and from the pains in the limbs, chills, headache, and thirst, thought myself commencing with typhoid fever. Soon, however, the genuine rusty sputa decided the nature of my trouble. The whole lung, from apex to base, became dull, but nowhere flat; breathing became difficult, and the constitutional symptoms all proportionately severe. The rusty sputa was throughout as characteristic as I ever saw it, and very copious, lasting for about eight or nine days, after which it changed to be thick, yellow expectoration, just such as is discharged on the breaking up of a heavy "cold." The cough is all the time becoming less, only troubling me now in the morning when I rise, and the expectoration is first a little thickish yellow mucus, followed by a little stringy, transparent and frothy mucus, such as one sees in the early stages of bronchitis. I should say here that after the inflammation had subsided, I was taken one morning with a severe fit of coughing, and expectoration of a few streaks of blood, followed by another short piece of the membrane. One morning since then I had a severe fit of coughing, but no blood nor membrane. I feared such an inflammation would surely break down the lung-tissue in the vicinity of the tubercle, and matters would grow rapidly worse, but up to this time such does not seem to be the case. I have watched the expectoration very close, and I cannot find anything of the nature of pus. I am also quite sure I can breathe better with the side than formerly, and Dr. B., who attended me, says the lung is far more resonant. I took the quinine all the time my lung was bad, for I was so weak, and have only discontinued it for a few days, my appetite now being very good, and I am feeling well otherwise. When I say feeling well, of course that is comparatively so. The whole lung feels weak yet, and is easily irritated by cold air. There are also some sort of aching pains in the shoulder and at the base, in the region of the liver. All things considered, I am much astonished at being so well as I am.

Yours very truly,
—, M.D.

AUSTIN FLINT, M.D., &c., &c., New York.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 5, 1874, to January 17, 1874.

CAMPBELL, A. B., Assistant-Surgeon.—Assigned to duty at Fort Clark, Texas. S. O. 4, Department of Texas. January 8, 1874.

Medical Items and News.

NEW INSTRUMENTS.—Through misapprehension, we credited the invention of the new scissors to Messrs. Tiemann & Co., instead of to Haywood Smith, and also the pocket illuminator, which we believe is the device of Roberts, of London. The improvements made by Messrs. Tiemann consist in an arrangement to fix the blades of the scissors at any required angle, and in the case of the pocket-lantern to make the same portable and furnish a sliding bull's-eye.

THE LATE DR. JOHN E. STILLWELL.—The East River Medical Association, at a recent meeting presented a full account of the life and services of the late Dr. Stillwell, from which, in view of the impossibility of publishing the sketch entire, we present the following points: He was born in 1803, graduated at Columbia College in 18—, at the College of Physicians and Surgeons in 1836. He was married to Miss Elizabeth Gillies in 1844, and the union was blessed with three daughters and a son, who survive him.

"Dr. Stillwell was a man of very few words. One had to get within his inner life to know him; but those who knew him best, loved him the most. His business was a laborious one, engaged as he was largely in obstetric practice. He was truly a worker day and night, making sometimes as many as fifty calls in the day. In the year 1869, he moved to his late residence in 12th street, where he hoped through distance to escape a great deal of daily work, and in the quiet of his home to reap the rewards of his previous labors. He had just fairly settled himself, and bid fair for years of comparatively quiet life, when he was stricken with paralysis a year ago last fall, and although partially rallying, was never enabled to attend to his professional duties; and after spending the summer in the country, returned in the fall apparently benefited; but gradually the powers of his system failed, his mind became weaker and weaker, and on the 26th of November he died."

The following preamble and resolutions were unanimously adopted:

Whereas, This Society has again been called to mourn the loss of one of its earlier members, John E. Stillwell, who after months of protracted illness died November 26th, 1873, therefore, be it

Resolved, That in the death of Dr. Stillwell this Society has lost one whose sterling qualities as a man, and ability as physician, endeared him not only to his professional brethren, but to the community at large.

Resolved, That although seldom able to meet with us in our deliberations, from the protracted and excessive labors of his daily professional life, we who knew him best felt that he had the interest of this Society at heart, and was always deeply interested in its success.

Resolved, That these resolutions be entered in full on the minutes, and that a duly authenticated copy of the same be transmitted to THE MEDICAL RECORD and to the family of the deceased.

MEDICAL LIBRARY SOCIETY OF HARTFORD, CONN.—At the last Annual Meeting, Dr. W. A. M. Wainwright was elected President, Dr. C. W. Chamberlain, Secretary, and Dr. H. P. Atherton, Librarian.

ARMY STAFF RANK.—CHAUTAUQUA COUNTY MEDICAL SOCIETY.—At the Semiannual Meeting of this Society, Dr. A. Waterhouse, President, in the chair, Dr. J. Andrews presented the following, which was adopted:

"*Resolved*, That our representatives in Congress be respectfully requested to exert their influence in favor of the bill now pending before the Senate and House of Representatives, entitled 'A Bill to Increase the Efficiency of the Medical Department of the Army.'"

DEATH OF THE SIAMESE TWINS.—The famous Siamese Twins, Chang and Eng, died at their residence in Surry County, North Carolina, on the 17th inst. Chang had an attack of paralysis last fall, which greatly en-

feebled his body and clouded his mind. They retired as usual on Friday night, the 16th inst. Chang was found dead in his bed the next morning, and Eng survived him only about two hours, dying, it is thought, of fright. Both were married and left large families, having lived to a ripe old age.

These singular beings were born of Chinese parents, in Siam, in 1811, and were purchased of their mother at Meklong, a city of Siam, in 1829, by Capt. Coffin and Mr. Hunter, who brought them to this country. Their bodies were united by a band of flesh stretching from the end of one breast-bone to the same place in the opposite twin. After realizing a competence by the exhibition of themselves in this country and in Europe, the Siamese twins purchased a plantation near Salisbury, N. C., where they resided until their death. They married sisters, and had five and six children respectively. Owing to domestic quarrels, two houses were found necessary, each living with his wife a week at a time alternately. They attended a Baptist church in their neighborhood, and were considered very worthy members. Almost since their arrival in this country scientists have been puzzled to determine how far the twins were identical, and their death adds little to what has already been known, except that it tends to confirm the opinion of some eminent London surgeons, that their separation by surgical means would have been fatal to both. It is now thought, however, that the ligature might have been divided after Chang's death, near his body, and that the life of his surviving brother might thus have been spared. A dissection of the bodies, which is promised at Philadelphia, will be of interest to every medical man throughout the civilized world.

CONTAGIOUS DISEASES.—The Sanitary Superintendent makes the following report:

SANITARY BUREAU, January 10, 1874.

The Superintendent begs leave to call the attention of the Board to the fact, that the reporting cases of contagious diseases coming under their treatment is quite imperfectly performed by the medical practitioners of the city. The Board relies chiefly upon them for such information as will enable it to discharge its duty towards them and the public in this important direction, and while in the main they have co-operated with the Board in this respect, the number omitting such reports is undesirably large.

For example: during December, 1873, there were 319 deaths from contagious diseases reported to this bureau, of which number but 131 had been previously reported as being sick. There were, therefore, 188 unreported cases, of most of which we should have had no knowledge whatever but for their fatal termination, and the necessity of stating the cause of death upon the death-certificate. The whole number of contagious diseases reported for that month was 667, including the 319 fatal cases above mentioned. If we subtract the latter from the former, we find that 348 cases were reported as sick. If this report embraced all cases of contagious diseases occurring in that month, this would show a fearful mortality indeed.

It is not intended to convey the idea that physicians are, at present, unusually derelict in this regard, the contrary is true; but it has incidentally come to the knowledge of the inspectors that there is still room for great improvement.

The profession theoretically recognizes the usefulness of statistics in medical as in other matters, but to be valuable these should be accurate. Accuracy can only be attained by the cheerful co-operation of physi-

cians, and when we consider at how little cost this might be given, it does not seem too much for the Board to expect.

Apart from statistics, however, private practitioners have seldom the time, the authority, nor always the inclinations to search for the causes of these diseases or the attending circumstances in particular cases, and to employ broad preventive measures.

Neglect in reporting cases is sometimes excused on the plea of poverty; but if contagious diseases are so prevalent as to make the postage onerous, the Board ought certainly to know it. Sometimes patients are reluctant to be exposed to the slight publicity of having their name, address, and disease entered in the book of the Board, the physician forgetting that his silence subjects him to a penalty. Oftener this neglect is due to forgetfulness, or to the absence of printed blanks, which are supposed to be indispensable. Blanks are always furnished when applied for, but we cannot be supposed to know the condition of each physician's supply.

When new blanks are printed I propose to back them with the section of the Sanitary Code referring to the subject, together with the amount of penalty which may be collected on its violation. I would most respectfully ask the Board to adopt such additional measures as, in its judgment, will secure a fuller record of those sick with contagious diseases.

All of which is respectfully submitted.

WALTER DE F. DAY, M.D.,
Sanitary Superintendent.

THE LATE DR. JONAS P. LOINES, OF NEW YORK.—The special committee of the New York Medico-legal Society appointed to draft appropriate resolutions relative to the death of our late fellow-member, Jonas P. Loines, M.D., through Dr. R. J. O'Sullivan reported as follows:

Whereas, The New York Medico-legal Society has learned with profound regret of the death of an esteemed member, Jonas P. Loines, M.D., and whilst yielding due reverence to the will of the Almighty, we desire to place on record a tribute of respect to the memory of our deceased brother; therefore be it

Resolved, That in his eminent abilities as a scientific investigator, unwearied energy and amiable character, we recognize the qualities that constitute a physician whose devotion to the discharge of his duties endeared him to all who knew him, and entitled him to the respect and affectionate remembrance of his associates.

Resolved, That these resolutions be entered in full on the minutes, and that a duly authenticated copy of the same be transmitted to the family of the deceased, and be published in the various medical journals.

RICHARD J. O'SULLIVAN, M.D.,
THOMAS C. FINNELL, M.D.

CLARK BELL, Esq., President.
G. W. WELLS, M.D., Secretary.

NEW YORK PATHOLOGICAL SOCIETY.—The following officers have been elected for the ensuing year: Dr. H. Knapp, President; Dr. J. Lewis Smith, Vice-President; Dr. Geo. F. Shrady, Secretary; and Dr. John H. Hinton, Treasurer.

DR. SPEIER, of Fulda, has been secured by the Japanese government as Professor of Natural Sciences at Yeddo.

THE AUSTRALIAN MEDICAL AND SURGICAL REVIEW is the name of a new monthly journal, or rather of a journal which has been re-established after having for some time ceased to appear.

Original Communications.

LARYNGEAL PHTHISIS.

READ BEFORE THE MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

By R. P. LINCOLN, M.D.,

NEW YORK.

Much confusion has resulted from the use of the term laryngeal phthisis; but for the want of a better we will adhere to this, and at the same time will endeavor to describe the conditions that we would embrace under it. Formerly under the term phthisis were placed nearly all the diseases to which the human frame was liable when there was a tendency to a wasting of the tissues, writers justifying themselves by keeping in mind the Greek *phthis*, to waste, and marshalling together every disease where this symptom obtained. Latterly doubt as to its significance has also been engendered by an attempt, in the opposite direction, to limit its applicability only to those cases where there was contemporaneous tubercular disease in the lungs.

Than to take either extreme it seems to us more in accord with our advancing knowledge of disease to adopt a more moderate view. In doing this we would wish to have abandoned the idea that a phthisis is necessarily tubercular, that a laryngeal phthisis is always a local tubercular deposit, or the result of any specific disease of which it is a local manifestation. We can then allow ourselves to look upon it as the result of a combination of morbid tendencies, both local and general, and define it as an inflammatory affection, attended by thickening and ulceration which tends to the impairment and destruction of the larynx and adjacent parts, and especially influenced by any cachexia.

Though laryngeal phthisis must have existed as a disease synchronous with pulmonary phthisis, yet, owing to the early vagueness of physical diagnosis, and the obstacles to post-mortem examinations, we find the first reference to it, and that very indefinite, by Galen. It was not till this century had passed its first decade that any undoubted and detailed account of it is found, and it is almost only within the period of the last decade—that of the laryngoscope—that our previous knowledge has been of much practical account.

Hippocrates does not mention it.

Galen's account is calculated to excite doubt in our minds, for he speaks of the affection as of little importance, and his report of its pathology is not at all like what we now know to obtain in the organic alterations of the larynx.*

Morgagni does indeed refer to laryngeal phthisis; but while he speaks of ulceration of the trachea, and reports at length several cases of tracheal phthisis, giving an account of the manner of respiration, the character of the sputa, and the appearance of the throat, yet he does not apply to the ulceration of the larynx the reasoning that leads him to call tracheal phthisis a special affection. He concludes that many of the reported cures of phthisis (pulmonary) were probably tracheal.†

Borsieri was the first to proclaim that the larynx may become ulcerated to the extent of producing hectic and death.

M. Duple proved the existence of laryngeal phthisis with pulmonary phthisis, and that laryngeal and tracheal phthisis differed only in situation.‡ Cayal, on the contrary, thought the two essentially distinct; but his

account of the symptoms of tracheal phthisis apply equally well to laryngeal phthisis.*

Louis, in his work on phthisis, published in 1825, gave accurate and careful observations on the pathology of laryngeal phthisis.

Nothing further of importance was added to the knowledge of this subject till the invention of the laryngoscope, since which time we have been able to study upon the living patient that condition which before was only contemplated after ulceration had run its course, and the interference of the physician was no longer called for.

Now erosion, congestion, and thickening, described by Louis, as preceding or accompanying ulceration and necrosis, can be combated before total destruction has preoccupied the ground, and while there is yet opportunity, if not always to cure, at least to delay the fatal termination and assuage the pain of the suffering patient.

PATHOLOGY.

To enable us the better to study the pathological manifestations of this affection, let us review in brief the opinions of men eminent in this department, who have essayed theories founded upon their respective interpretations of morbid action in these parts.

Rokitansky, when speaking of laryngeal phthisis, says: "It is so rare, we are inclined to doubt its existence," but describes its appearance when present as follows: "It is either deposited in the form of gray granulations in the submucous areolar tissue, or, as yellow, caseous, friable, tuberculous matter, is infiltrated into the mucous membrane; in either case, and especially in the latter, it rapidly softens, and ulceration is established."‡

He, however, does not think the thickening of the epiglottis can be accounted for in this way.

Mackenzie, through a very large experience, has "never seen the gray granulations referred to."†

Contrast with this the following conclusions arrived at by Louis, after making 295 post-mortem examinations, especially considering this subject: "I have not in a single instance met with tuberculous granulations in the substance or on the surface of the epiglottis, larynx, or trachea; so that inflammation must be regarded as the most frequent cause of the ulceration of these parts." "However, as I have already said, the irritation or inflammation due to the continual passage of the contents of cavities is not the sole cause of the ulceration we have been examining, for, though rarely, these ulcerations do exist in cases where there are no cavities."§

Further on he states that he has never observed such ulceration in cases of gangrene of the lung, where the matter would reasonably be supposed to be particularly irritating, unless tubercles existed.

M. Andral considered the mucous membrane of the larynx a frequent seat of tubercular deposit in phthisical subjects, though located in the follicles; and he attempts to controvert the deductions of Louis.||

Niemeyer "hesitated to admit any ulcers as tubercular in which the disease, instead of springing from isolated nodules, develops from diffuse degeneration of the mucous membrane."¶

After describing all the symptoms of pulmonary phthisis, he says: "All these symptoms, however, will not warrant a diagnosis of tubercle of the larynx, unless we are able to show that the lungs too are af-

fected. They are all capable of being produced by other kinds of laryngeal degeneration.**

Cruveilhier and Röhle doubted the tubercular character of laryngeal phthisis, because they could not establish the caseous state of that lesion.†

Virchow, according to Krishaber and Peter, has observed in these ulcerations a proliferation of cells, agglomerating and passing through the same changes as tubercular granulations; and, confirming the opinion of Rokitsansky, says: "The larynx is recommended to those who wish to recognize true tubercle."‡

Virchow, in a letter (Oct. 9th, 1868) to the authors of the article referred to, says: "I am certain laryngeal phthisis is due to tubercularization of the mucous membrane in the form of little, gray, transparent corpuscles, and is composed of lymphoid cells."§

He harmonizes the opinion of others by saying that owing to the exposed position of the larynx these tubercles give rise to superficial ulcers, and do not become caseous as elsewhere.¶

MM. Hérard and Cornil maintain that the microscope gives conclusive evidence of the presence of tubercles.¶

Such conflicting views among authorities so eminent may be considered conclusive that there is no one pathological state uniformly present. In fact, we have repeated the old warfare of the theory of pulmonary phthisis; and, as in this case, it is not impossible to harmonize apparently different theories by adopting a doctrine suggested by Isambert, who proposes the identity of pulmonary phthisis with the different forms now recognized and several phases of laryngeal phthisis.**

CLINICAL HISTORY.

The different tissues that together constitute the parietes of the larynx afford us examples in laryngeal phthisis of every stage of inflammation, viz.: simple redness, swelling, erosion, ulceration, and, as sometimes happens to the cartilages, necrosis and caries.

The first effect of inflammation on the mucous membrane of the larynx, as elsewhere, is a change of color. In health its color is about the same as that of the interior of the lip, namely, a pale rose, but at the onset of an inflammation it changes to a deep red, or even purple; the depth of color depends on the intensity of the inflammation, whether it is acute or chronic: in the latter state the color is not so intense as in the former; its intensity is also modified by the location of the inflammation, as upon the vocal cords. Wherever the submucous tissue is scant and the mucous membrane firmly attached, the increase of color is but slight, whilst in those parts that are loosely attached the same degree of inflammation will be attended by a deeper coloring.

This change in color is not always permanent, i.e., after death the same laws obtain as in hyperemia of other parts. To illustrate this we need only refer to the post-mortem changes that occur to papules, chemoses, etc., where pallor succeeds to the bright color that was present when the vital functions were still active. This fact, namely, non-permanence of color, has probably led to many discrepancies in accounts of post-mortem appearances, and erroneous inferences drawn therefrom.

¶ De la Phth. Pulmon. 1867.

** Comptes-rendus de la Soc. de Méd. des Hôpitaux, 27th Dec., 1872.

This redness may extend throughout the larynx or be confined only to a small part. Frequently only the laryngeal surface of the epiglottis will be involved, or perhaps only the bottom of the ventricles. Its presence may usually be inferred, when we have no more positive proof, from an excess of mucus.

The opposite condition, that of anemia, is often observed, particularly in emaciated subjects and those in the incipient or advanced stage of phthisis pulmonalis. This state does not render the presence of ulceration in some part of the larynx improbable, and we should not ignore this fact while making our examinations.

Succeeding redness we have an increase of thickness. The mucous membrane itself becomes swollen and soft, not only from the large amount of blood attracted to the part, but also on account of the infiltration of serum within its substance. But the tumefaction depends chiefly on the infiltration of the submucous cellular tissue, which in this affection readily partakes of the inflammatory action of the contiguous mucous membrane, or it may be itself the primitive seat of the morbid action where this texture is abundant and loose, as on the anterior side of the epiglottis, the aryteno-epiglottidean ligaments, and lips of the glottis. When the inflammatory action is of a more chronic character, its product may be plastic rather than serous, in which case the mucous membrane will become denser, hypertrophied, and frequently uneven, while, when considerable serum is effused, it becomes pulpy and soft, and easily breaks down, presenting a condition characteristic of another stage.

When the inflammation has its primitive seat in the submucous cellular tissue, the appearance of the mucous membrane, except the general fulness, exhibits but little alteration from normal, and in color may be even paler.

If the first conditions of redness and swelling persist, we have, sooner or later, a state first recognized and described by Louis as erosion. They exist wherever, from superficial inflammation, the epithelium has been destroyed, and are usually circumscribed. The villi may themselves be removed at the same time with the epithelium, in which case the mucous membrane will appear slightly depressed, and the color at that point, especially at its base, a little lighter than the surrounding. Usually, however, they persist, and present a bright-red, velvety appearance. Erosions are best recognized, according to Louis, by floating the specimen in water, when, according to Trouseau, the villi will stand out like the "villi seen on a dog's stomach." These villi often hypertrophy, a part being destroyed, and resemble granulations, and doubtless are often considered tubercular.

These erosions pour out a muco-purulent secretion, and when they have attained the condition resembling granulations, bleed readily to the touch.

More important than the preceding, and of a class of which erosions may be considered the first steps, are the true inflammatory ulcerations. The inflammatory process progressing, the vitality of the denuded mucous membrane soon becomes impaired, and the villi even becoming destroyed, we find an excavated ulcer with a base of submucous tissue. This latter, in turn, soon gives way, and the remaining subjacent organs form successively its base until the various cartilages are exposed or involved, and finally yield to the destructive process. This ulceration may extend not only in depth, but also in periphery, until we sometimes find the whole internal surface of the larynx involved. When the ulcers are small they are usually round in shape, but when large are oftener irregular, and may be formed by the union of several small ones. They

may be looked for in any part of the larynx, a favorite seat being at the arytenoid commissure and sides of the arytenoid cartilages; they are not unfrequently found upon the vocal cords.

While the effect of an erosion may be completely repaired, the cicatrix of the wound of an ulcer presents a puckered appearance, or, when extensive, its location is represented by a thin film of connective tissue, and, according to Ryland, is never healed by granulation.*

There is another form of ulceration, undistinguishable from the latter in its advanced stages, but which has a beginning pathologically distinct. As we have already seen, mucous glands are numerous, and often quite large in different parts of the larynx, and we should be prepared to find them subject to the same pathological changes as similarly constituted glands elsewhere. When they are first involved in morbid action, either when it is limited to its own substance or when due to an extension of inflammatory action from the adjacent tissues, they appear as small elevations, the size of a pin's head, with the mucous membrane covering them, shining, tense, and of a light color. If the contents of this little cyst is evacuated at first, it is found to be thicker than normal mucus, and honey-like; but later, if they retain their continuity, the contained secretion in rare instances becomes still more inspissated, and even cheesy.

It is this condition that we can easily understand might be mistaken for miliary tubercle in or on the mucous membrane, and has even been described as such by some recent writers. This same condition, never more strikingly apparent, is not unfrequently found accompanying an anemic state of the larynx where mal-nutrition is present.

In the inflammatory state especially, the walls of these glands are unable to resist the tension from within, and finally give way when a small ulcer marks the site of each. If the degree of inflammation is considerable, the vitality of the contiguous tissues becomes enfeebled, and the destructive action will enlarge this newly formed ulcer, when its appearance and progress will be the same as the true inflammatory ulcer described above. In this form of ulcer, too, the papillae will often appear on its border, become hypertrophied, and resemble red hemorrhagic tubercles.

Follicular laryngeal phthisis may appear independent of inflammation of other tissues, but is seldom if ever absent when the other tissues are primarily affected; and its location may be any part of the mucous surface except the vocal cords. These follicles are isolated upon the free border of the epiglottis, but increase in number till they become aggregated at its base.

When the cellular tissue of the larynx has become involved in a high grade of inflammation, instead of its terminating in resolution we may have an abscess, and particularly is this liable to happen if the perichondrium becomes involved, in which case we may have either caries or necrosis of the cartilage even to the extent of their complete destruction and expulsion.† In consequence of these abscesses opening through the mucous membrane we may have ulcerations of a fistulous character, not unlike in their history and progress anal abscess and fistula, at the bottom of which diseased cartilage will often be found. They usually open into the larynx, but sometimes they discharge their fetid contents into the œsophagus or pharynx.

Whatever be the origin of the ulceration, it may extend to and invade any of the cartilages of the larynx, and one or all may be affected. The loose cellular tissue by which they are surrounded, as we have seen, easily loses its vitality, and any deposit of pus immediately in their vicinity destroys their nutrient connections, and they consequently soon perish in whole or in part.

During the process of inflammation here, the cartilage is transformed into a bony substance, if a part of its nutrient supply is preserved, while another portion crumbles away, or, according to Porter, an earthy deposit similar to that in degenerated arteries takes place.* An entire cartilage may be thus transformed, when it acts as a foreign body, and an abscess results, which, examined after death, is found to contain pieces of carious bone—white, unorganized, fetid, and spongy. A greater part may have been expectorated before death, but some remnants of the debris will usually be found.

The arytenoid cartilages are most frequently affected, and after them the hard portion of the cricoid. Necrosis is usually a result of an abscess, while caries results from an ulceration starting in the mucous membrane; the former, according to Trousseau, is more common among adults, and the latter among children.‡

Edema, to some extent, is always present with any considerable degree of inflammation; and, though this is but a symptom, and, so to speak, an accident, of the morbid action, it may of itself become the cause of death.

Rarely, if ever, do any one of these pathological conditions occur singly. In any larynx where, for instance, we have caries, we find ulceration of the mucous membrane and cellular tissue, and with this, with rare exceptions, edema and engorgement of the mucous membrane, together with follicular inflammation.

The epiglottis, being similarly constituted and subject to the same influences, is liable to the different morbid actions above considered, except necrosis. Its mucous membrane becomes thickened and indurated, as well as thickened and softened, and in either case the organ may become two or three times thicker than normal, and lose its flexibility.

While the minor degrees of ulceration are here less common than in other parts (probably because of the paucity of the muciparous glands in its upper part), the deeper forms of ulceration are more prominent in their effects and quite destructive. It is common to find it much distorted by previous inflammation, and it may be even perforated. Ulceration and caries of its border result in a gnawed appearance, and may effect its total destruction.

Rees reports in *The Lancet* of March 17th, 1860, a case of strumous ulceration of the larynx, with destruction of one-half of the epiglottis; and the same journal of April, 1868, contains an account of a case with the epiglottis totally destroyed, and the wound healed. In neither of these cases was there any impairment of the voice, and but little difficulty in deglutition.

We can add to these, two cases of total destruction of the epiglottis, attended with only slight hoarseness, and but little difficulty in swallowing.

The above-described changes, that have been spoken of as belonging to the larynx, are found, under like circumstances, in the trachea, and M. Cayol has written a well-known thesis descriptive of them, under the

§ Rokitsansky. Op. cit., vol. III., p. 280.

title of Tracheal Phthisis, in which he attempts to prove it to be a primitive and tuberculous affection.*

Laennec states that ulcerations of the trachea are much more common in perfectly healthy than phthisical persons, which statement Louis pronounces erroneous, and attributes to an error of memory.†

The mucous membrane above the larynx being histologically the same as that below, is subject to the same morbid actions as the larynx itself.

Bonnet says the mucous membrane of the larynx is as liable to the same changes as all other similar membranes, and is as frequently involved.‡

Statistics upon this point, except in the case of phthisis pulmonalis, are not very satisfactory, and will not be more so till the laryngoscope is in more general use; even in these subjects we have but few sources to draw from, for comparatively few observers of autopsies have noted the condition of the larynx. The number, however, is amply sufficient to convince us that laryngeal ulceration, in whatever tissue it may have had its birth, or whatever may have been its morbid cause, is particularly common in subjects of pulmonary phthisis. Andral states that in three-fourths of the phthisical patients treated in the wards of M. Lermier, the larynx was affected in different degrees.§

Louis gives, in his work on phthisis, the following results of 295 examinations: Ulceration of the larynx, 29 per cent.; of the trachea, 36 per cent.; and of the epiglottis, 18 per cent.

Trousseau and Billoc report five cases where examinations of the lungs were made, and no tubercles found, where death is presumed to have occurred from an affection of the larynx, attended with an ulceration of its investing mucous membrane.||

Porter reports four cases of disease of the cricoid cartilage that proved fatal,¶ and M. Cruveilhier five similar.**

Of 23 cases of consumption, in which the larynx was examined, Ryland found 44 per cent. with ulceration.†† S. Scott Alison, out of 26 cases, in all stages of consumption at one time in the hospital, found 73 per cent. were suffering from disease in the larynx, and of those in the third stage a per centage of 83.‡‡

Of 19 cases of laryngeal phthisis, in our private practice, 14, or 73 per cent., had accompanying pulmonary phthisis; 9, or 47 per cent., would be classed as scrofulous. In four cases ulceration existed on the left side only, and in three on the right; six of these seven were in patients suffering from pulmonary phthisis, and all were affected on the side of the only or greater diseased lung. In the remaining twelve cases the ulceration was situated either in the commissure, or on both sides at the same time.

ETIOLOGY.

That hyperæmia, erosion, and ulceration of the mucous membrane of the larynx may be precursors of the deeper and more destructive morbid changes, every observer will admit, and hence, in looking for the cause, anything that leaves behind the superficial disease must be regarded as a possible step in the forms to be dreaded, and attended with danger both to the healthy physiological action of the part, and even to life itself.

Whether laryngeal phthisis, in all the different stages we have described, occurs idiopathically, is a

question open to discussion; that it occurs symptomatically has generally been the accepted theory. Amongst the advocates of the former theory may be mentioned Laennec, Cayol, Rokitsky, and Trousseau, while Louis, Niemeyer, Mackenzie, and many others support the latter.

That the less important pathological manifestations often occur without being followed by the more destructive conditions, comes within the observation of every one, as is witnessed most commonly in acute catarrhs of the larynx, as a consequence of heart-disease, and after different fevers; but whether these same appearances are the preliminary steps to, and will pass into, the more serious ulcerations of the deeper tissues, is a point of vital interest. To decide this we must extend our inquiries and investigations beyond the larynx, considering the general condition of the patient as well as the period the disease has existed in the larynx.

Ulceration of the mucous membrane, as well as of other parts, is a frequent consequence of acute inflammation; but whether this be the cause of the disease we are considering, or whether it supervenes on a chronic inflammation, or is induced by irritation in a distant part, as in pulmonary phthisis, or depends on a local tubercular deposit, neither its locality nor its appearance will alone determine.

Hence, we must include among the exciting causes the same conditions that result in acute as well as in chronic inflammation of the larynx, and which usually tend rapidly to recovery. Among these are cold and moisture, whether inspired or applied externally, as a draught upon the neck, or a neglected wetting of the feet. The simpler forms of the disease are particularly liable to be aggravated by efforts at public speaking, or violent coughing, and thus an inflammation, that was at first of a superficial character, and that otherwise would naturally pass off in a few days, will assume a chronic course, and perhaps extend to the deep tissues. Particles of inhaled dust, or other irritating substances, will frequently induce disease of the larynx as well as of the lungs themselves; imprudence in dress, from too free exposure of the neck, particularly in ladies. Prof. Alison, of Edinburgh, many years ago recognized this fact, and deprecated the practice of shaving, highly esteeming the beard, both as a protector of the throat, on account of warmth, and also because it served as a natural respirator; and he advised the stonemasons, particularly, to wear it, to filter from the respired air the particles of dust.*

Louis, at one time, following the opinion of Sylvius, attributed all these morbid appearances to the contact of sputa from the lungs, that was constantly passing over the mucous membrane of the larynx in cases of phthisis pulmonalis. His reason for this inference was, that this condition oftentimes presented itself on the posterior part of the larynx, and also of the trachea, in his examination of patients that had died of consumption. Afterwards observing a few cases where this condition was not present, and there was, nevertheless, ulceration, and also, as we have already seen, failing to find it in cases of gangrene of the lung, he was compelled to admit that there must be additional influences at work.

Though, fortunately, there are many cases of pulmonary phthisis that escape ulceration of the larynx, yet frequent observation will convince one that it only appears, in many cases, subsequent to the disintegration of the lung-substance, and after purulent expectoration has been established. That the contact of pus ought to be considered one of the causes of this affec-

* Edinburgh Med. Jour., Dec., 1861.

tion, in addition to the coincidence already noted, is rendered probable from the analogous fact that we often find the integument itself excoriated and ulcerated from being constantly bathed in pus for a long time. In addition thereto we could cite several instances of cases that we have treated where ulceration of the larynx could only be explained by the contact of pus that had run down over the pharynx from the posterior nares in posterior nasal catarrh.

Exceptionally, inflammation and its consequences may appear in the larynx by reason of its extension through the continuity of surface from the pharynx, and possibly from the trachea; but when this occurs there are probably other determining causes of a constitutional nature at work that are of a progressive character. We have already seen how cases of pulmonary phthisis in its advanced stages may have a considerable influence in inducing ulceration of the larynx, but there are still a large number of cases where morbid action is already established in the larynx before the stage of purulent expectoration has been reached.

A full appreciation of this fact is of paramount importance, and upon an early recognition of this state will often depend the future welfare of our patient. In this respect it must be acknowledged that the first evidence of the laryngeal may be but a precursor of a more formidable trouble in the lungs; both may be due to the same cause, first recognized in the larynx by the aid of the laryngoscope, before the disease in the lungs has had time to work changes there so great as to be detected by the means at our command.

Therefore, notwithstanding the many causes we have seen may in turn be considered responsible for some of the different phases of laryngeal phthisis, we would name another, which, so far as we are informed, has been altogether ignored, but which, nevertheless, may reasonably occupy a place in our list that would otherwise remain incomplete; we refer to the phenomenon of reflex action.

Prof. Brown-Séquard, in his work on the "Physiology and Pathology of Nervous Centres," shows the great power of this influence in the modification of secretion and nutrition as seen in conditions of congestion or anemia, hypertrophy or atrophy, and ulceration. He has supported this theory both by actual experiment and by citing many unquestioned cases, among others, instances of orchitis due to irritation of the ureter by a calculus; of inflammation of the stomach from irritation of the filaments of the par vagum in the cesophagus; of pleurisy due to an irritation of the nerves of the breast by some operations;* and of two cases of peritonitis and death from an operation of the cervix uteri without intercurrent inflammation of the uterus or vagina.† There are numerous instances of inflammation of one eye extending from irritation into the other. Dr. Cain, of Charleston, reports cases that seem to show that croup may be produced by a reflex action starting from the stomach.‡

These secretory or nutritive reflex phenomena occur chiefly through two modes of action; by one the nervous system determines an increase in the attraction of blood to the tissues, when we have a congestion and its consequences; while by the other, the force, instead of acting on the parenchyma of the tissues, operates upon the walls of the blood-vessels and produces a contraction which results in anemia and its sequelæ.§

This action through a centripetal nerve to a centre

is reflected back by a centrifugal, preferably starting from the same segment.* The lungs and larynx occupy relations fulfilling these conditions essential to the exercise of this phenomena, their nerves being the pneumogastric and spinal accessory with a free anastomosis from the sympathetic.

The great abundance of this nerve-supply to the larynx is often noted, but its significance not fully understood. Luschka speaks of their remarkably free distribution in its mucous membrane terminating in oral bodies, and others provided with numerous ganglion-cells.†

From this it seems we have here eminently a field of reflex action; in fact each movement of respiration is an illustration of it, and though doubtless these nerves have other important functions, that they must be chiefly instrumental in the reflex phenomenon of coughing as well as of any organic change therein often found, is supported by reason as well as by analogy.

Another argument in support of the theory that reflex action from the lungs sometimes exercises a controlling influence in the modification of nutrition in the larynx, may be inferred from the fact that laryngeal phthisis usually commences on the side corresponding to the pulmonary disease.‡ A similar inference may be drawn from the fact that paralysis of one vocal cord, without ulceration, which sometimes occurs in cases of pulmonary phthisis, is almost always on the side corresponding with the diseased or greater diseased lung.

The excessive pain in the larynx that is often experienced by patients in the last stages of pulmonary phthisis, though there may be no lesion discoverable there, is also significant in this connection.

The inflammation and ulceration of the mucous membrane and soft parts of the larynx may itself be a cause, when once established, of further destructive disease.

When the inflammation has extended to the perichondrium this may become inflamed to a large extent, when, as happens in analogous cases with the periosteum, we have a death of the contained organ, which, acting as a foreign body, in turn gives rise to an abscess. At other times the ulcer will burrow to and through the perichondrium, and, encroaching upon the cartilage, we may have caries. In this case there seems to be a strong effort at repair, which shows itself, according to Trousseau,§ in the incomplete ossification which always takes place, and which is not observed in necrosis, where the severance of nutrition is overwhelming from the first.

The influence of the scrofulous diathesis is often apparent in this affection.

The use of this term here may seem vague, but every one recognizes a vitiating, and often controlling, condition in some systems, of a constitutional nature, slow in its development, but attended with a tendency to disorganization of different tissues, as the cartilaginous, the glandular, the skin, and the mucous membrane. The latter, which in different parts are very liable to derangement, we find illustrated in frequent discharges from the nose, ears, eyes, fistulae connecting with mucous membranes, and in the organ we are considering, all its tissues from its mucous membrane to and including its cartilages. We further recognize two distinct varieties, the sanguine, with its clear, fair skin and delicate features, and the phlegmatic, with its coarse, dark, sallow skin and uninviting countenance. Perhaps it is only a coincidence, for

§ Trousseau and Belloc, p. 24.

the number is not sufficient to establish a rule, but of nine cases in our own practice of destructive ulceration of the larynx where struma assumed to be the controlling influence, seven would be classed among the phlegmatic.

In this subdivision of laryngeal phthisis it is common to find coexisting enlarged and diseased tonsils, and associated therewith an enlargement of all the soft parts of the pharynx, and frequently of the cervical glands.

Among the remedies that have been accused of inducing this disease, Drs. Graves and Stokes claim that in enfeebled constitutions any disease of the larynx may terminate in ulceration of its cartilage if mercury is used.*

Syphilis is a very frequent cause of destructive ulceration of the larynx, but it is beyond the limits of our plan to consider this extensive part of the field in detail, and we shall only refer to it under diagnosis.

Hereditary influence should not be so generally ignored among the causes.

When we find in the same family, in successive generations, unusually large noses or ears; or, if you please, supernumerary fingers or toes, analogy, at least, would lead us to expect in morbid changes in different organs the influence of transmission exercised, and though this is generally admitted in some of the more serious and pronounced diseases, as in pulmonary tuberculosis, yet in those less striking it is too often ignored.

We must not disregard the injurious local effect of the excessive use of tobacco and alcoholic drinks, or extremes of temperature in any drink, in one already predisposed to this affection.†

Age and sex have been considered among the predisposing causes, it being most common in middle life, and more frequent among males; but this greater frequency seems but natural, from the greater exposure to the vicissitudes of weather to which men are subject.

As for local tuberculosis ever being the cause of laryngeal phthisis, we think what has already been said under pathology is sufficient to prove how rarely this is the case, though the testimony to its occasional presence is too reliable to be questioned. On this point we will only quote the words of S. Scott Alison, which may be taken as an expression of our own experience: "Tubercular matter in masses even so small as mustard seeds, I have never seen in the larynx or trachea."‡

Whether pulmonary phthisis may cause laryngeal phthisis, or *vice versa*, is another question.

We have seen how frequent laryngeal phthisis is; in how many shapes it may show itself; under what conditions it appears; that it is frequently associated with phthisis of other parts, particularly of the lungs; that it may appear before, at the same time with, or after, the latter disease has been established; and it is natural to seek if there is any necessary relation between the two, and whether we shall array ourselves among the followers of Dauble, Cayol, Laennec, Borsieri, and Trousseau, who claim that laryngeal phthisis is the frequent cause of pulmonary phthisis, or with Louis, and many more recent investigators, who believe it is pulmonary phthisis that causes the laryngeal form.

It often happens that the most divergent opinions can be reconciled, and by compromising these two views we can explain many cases that would otherwise prove perplexing. We do not think it would always be proper to place the two diseases, when they coexist, in the relation of cause and effect. The number of instances of laryngeal phthisis that we have seen in its first stages,

when there was hyperæmia, erosion, and even ulceration, before any disease could be detected in the lungs, would lead us to attribute to each the same or similar causes, viz., a general diathesis, first showing itself in the most vulnerable part in a subject already predisposed by hereditary or acquired disposition. It is not unlikely the determining force in locating the first symptom of the malady may be either a cold in the throat, i.e., an acute laryngitis, or a cold in the chest, i.e., an acute bronchitis or pneumonitis, which once having seized hold of a system debilitated from any cause, makes it an easy prey.

(To be continued.)

A CASE OF ASPERGILLUS IN EXTERNAL AUDITORY CANAL.

By WM. D. BIZZELL, M.D.,

OF GAINESVILLE, ALABAMA.

This case occurs in my own person. It has been about two months since my attention was first directed to my ears by an itchy, slightly uncomfortably feeling, which provoked a constant desire to pick at them, the feeling being that of an accumulation of wax in the canal. However, the amount of the secretion was about normal, but in its consistency greatly changed, looking exactly like half-melted tallow, and having entirely lost that bitter unctuousness peculiar to the cerumen. It was not, however, always of this lardaceous consistency, but in dry and scaly masses like aggregations of cast-off epithelia. It was noticed that the uncomfortable sensations were exaggerated whenever the lardaceous secretion was most abundant, the dry and scaly condition being comparatively comfortable.

I treated it as a slight inflammation of the canal, instilling, in quantity sufficient to moisten the inflamed walls, glycerine in which a small quantity of carbolic acid was dissolved (gr. ij. to $\frac{1}{2}$ i.). It is, however, but just to state that the remedy was not used sufficiently often or with that regularity that would insure success, recourse being had to it occasionally when the attention would happen to be particularly called to the ear.

However, up to the 15th of the present month, November, nothing abnormal beyond what has been described was discovered in the secretions from either ear; no discoloration, no black specks, or anything of the kind. After riding on that day a considerable distance, with a cold, sharp wind from the north-west blowing upon the right side and into the right ear, the uneasy sensation in that ear became greatly intensified, feeling as though it were completely stuffed up, accompanied by a pain recurring every few seconds, as though some sharp instrument with a twisting, boring movement was penetrating the drum. There was also a headache like that of hemicrania all over the region supplied by the facial nerve of the right side, which was perceptibly hotter to the touch than the left.

A speculum was introduced, and a superficial examination made by a medical friend, but proved negative, beyond demonstrating a reddened and inflamed condition of the lining membrane of the canal. Any movements of the lower jaw, as in chewing, yawning, etc., produced considerable pain. On the morning of the 16th all the symptoms worse. So impressed was I that there was an accumulation of some kind in the canal, that I cautiously introduced Gross's ear-scoop, and succeeded in bringing away a piece the size of a pea of this lardaceous substance, upon the free surface of which was a delicate pellicle thickly covered with little black dots. Under an ordinary hand-magnifier I thought I could make out a fungous growth.

* Dublin Hosp. Reports, vol. v., p. 82.

† Similar unfavorable influences, we believe, attend the use of highly seasoned food, and a too free use of common salt.

‡ Morbid Throat, p. 8.

Detaching a small portion of this pellicle, it was carefully mounted in glycerine, on a glass slide, under cover, and submitted to a power of 250 diams., which showed its development and character perfectly, resolving the delicate pellicle into an intricate network of fibres, the mycelium of the fungus, and here and there the fruit-bearing stems crowned by their sporangia; the latter, by their globular shape and intensely black color, at once proclaiming it to be the *Aspergillus nigrigans*. A good deal more was extracted from the same ear, with the effect of giving complete relief to the symptoms, with the exception of a little stiffness, and soreness to the touch. The left ear felt but very little worse than it had felt for some time. Introducing the scoop, however, I thought I could detect in a portion of the matter removed some of the little black points, and microscopic examination showed the growth to have invaded this ear also. It was noticed that the point whence the specimen was obtained in the left ear was not nearly so deep in the canal, so near the tympanum, as that obtained from the right; in fact, there seemed to be only a small patch of the fungus in the upper wall of the middle portion of the canal. The hearing in neither ear was perceptibly affected. There is slight catarrh of the Eustachian tube of the right side. The treatment has consisted in thoroughly syringing the ear with tepid water twice a day; immediately after each syringing a delicate probe, on which is wound a small pellet of raw cotton, is thrust into the canal, till the free extremity of the cotton rests upon the tympanum. It is then gently twisted upon its axis several times, and withdrawn. This is repeated until the mop ceases to bring, on its withdrawal, shreds and flakes of that caseous and false membrane-like substance which adheres so closely that no amount of syringing can effect its removal. Then dipping one of these mops into equal parts of glycerine and water, in which is dissolved sulphate of zinc two grains to the ounce, the whole canal is thoroughly moistened with this mixture. The zinc acts on the inflamed and irritated membrane, bringing about a more healthy action. The glycerine serves to keep the medicament in a soluble state, and, constantly applied to all parts of the canal, also softening and rendering more easy of removal the cheesy exudation poured out; a thorough removal of which, together with all the sporules of the fungus, constituted the most important point in the treatment; for as long as there is a single spore the disease will return, provided it be left long enough unmolested to develop, which requires only a few hours. After the first discovery of the cause of the malady in my own case, no injections or other remedial measures were instituted for some eight hours, the removal with the scoop giving almost complete relief for the time. In about four hours, however, there would be a recurrence of the pain, and a fresh crop of the growth could be extracted.

In looking over the literature of this subject, I find Richardson, in his work on Medical Microscopy, barely mentions the existence of such a disease, and refers the inquirer to the January No. of the *American Journal Med. Sciences*, 1870, which contains a most valuable contribution on this subject from the pen of D. B. St. John Roosa, of New York City. After a careful study of this paper we find that our case coincides in all the main points with the two cases reported by Dr. Roosa, and has followed the clinical history of the disease as mapped out by him.

The inflammation which, on the authority of Schwartz and Wreden, is a necessary precursor of the disease, he infers from the history to have been present

in both of his, and was also present in my case. But I am inclined to think the fungus may exist for some time without giving rise to symptoms of sufficient gravity to demonstrate its presence, provided the growth be confined to the outer half of the canal, and no special care or attention be bestowed upon the secretion removed therefrom. When, however, the deeper and more sensitive portions of the canal become involved, including the outer surface of the membrana tympani, a new and more painful set of symptoms supervene. Thus, for the sake of experiment, my left ear was left untouched for several days, none of the secretion being removed except what could be easily brought away with the tip of the little finger; yet at the end of that time the sensations experienced in the ear were about the same as at its commencement, while a thorough cleansing of the canal showed that it contained a considerable amount of the fungus in all stages of development. On the other hand, after the thorough removal of the growth from the right ear with the scoop only, the characteristic pains already described would instantly cease, recurring only after the lapse of four or five hours, when examination showed the development of a fresh crop of the fungus. One or two of these specimens exhibited complete casts of the membrana tympani. We agree with Roosa when he says that this pain is a distinguishing feature in this affection, the other symptoms being also common to inspissated cerumen, and is caused by the germinations and fructifications of the fungus. For if the pain were caused by the inflamed state of the canal, why it is clear that it would have continued as long as the inflammation existed; but we have seen that such is not the case, the pain ceasing after a thorough removal of the fungus. The microscope is necessary to perfect the diagnosis. As to my method of removing the adherent exudation and of applying medication, I do not recommend it to be generally adopted in such cases; indeed I think that even in the hands of the most skilled it would be a hazardous procedure to enact it upon a patient; but to a person thoroughly conversant with the organ, guided by the sensations, the instrument in his own hand, with proper care, there is no danger. Roosa recommends its removal by forceps, the ear being well illuminated by a speculum. This is undoubtedly the best under all ordinary circumstances. The catarrh of the Eustachian tube is improving, no treatment being used except to inflate it frequently through the day by tightly closing the nose and mouth, and using forced expiration. The characteristic pains ceased at once, and no spores have been detected by microscopy since the fourth day after the inception of the treatment already detailed.

To the reader who desires a complete exposition of this subject, including the botanical relations of the fungus, I would refer him to Dr. Roosa's paper, already cited, or to the chapter devoted to this subject in his recent work on "Diseases of the Ear."

GAINESVILLE, ALA., November 27th, 1873.

ROCKLAND CO. (N. Y.) MEDICAL SOCIETY.—At the last regular meeting of this Society, Dr. William Govan was elected President; Dr. J. O. Polhamus, Vice-President; Dr. J. Wells, Secretary, and Dr. B. Davidson, Treasurer.

DR. GEO. M. LEFFERTS.—The cuts in Dr. Leferts's article in the last number were accidentally reversed. The laryngoscopic pictures should have been represented as seen in the mirror—that is, the epiglottis above and the arytenoids below.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

CERTAIN POINTS IN CONNECTION WITH THE SURGERY OF ARTERIES.

THE patient who gave occasion for these considerations was a man forty-five years of age, who had shot himself in the mouth with a pistol. The ball had passed from before backwards, from right to left, through the tongue, entered the mouth, and passed on into the posterior wall of the pharynx, lodging near the fifth cervical vertebra. He was admitted August 27th; the hemorrhage was very obstinate, but by means of ice, and chloride of zinc applied with lint, it was finally arrested. September 3d, hemorrhage returned. This calls out one practical point; and that is, cessation of hemorrhage is not evidence that the vessel is permanently closed. A vessel may bleed profusely and then cease, and then hemorrhage return as soon as the action of the heart is restored. The hemorrhage returned was not easily controlled, and ligation of the external and internal carotid arteries was resorted to, and thus far with perfect success. It is in the ligation of both of these arteries that the practical fact lies. There is one rule in surgery which is never to be gainsaid, except when the circumstances are such that it is impossible to follow it out. The rule is, a bleeding artery must be ligated above and below the point of injury, if accessible. Simple ligation of the cardinal extremity of the vessel is not sufficient, for the reason that anastomosis being so abundant, the liability is that blood will return in the wound from the distal extremity of the vessel. This rule can be well observed in cases where the artery can be reached, but cannot be applied when hemorrhage occurs from a bleeding artery in a space where it cannot be exposed. Such was the condition of affairs in this case. Several arteries had been wounded in the course that the ball had taken. Two methods of arresting the hemorrhage were left to be resorted to, viz., pressure or ligation of the main vessel. From the nature of the operation and the situation of the bleeding points, satisfactory results were not to be obtained by pressure. Ligation of the main vessel was therefore necessarily resorted to; and in resorting to this operation another practical point was developed. Ligatures were placed upon both external and internal carotid arteries. It might seem to be sufficient to ligature the common carotid artery alone, and thereby save the double operation and the difficulty attending it. But it has been found that ligation of the common carotid artery is not sufficient to establish a permanent arrest of hemorrhage from a wounded point in the continuity of the artery, by its branches above the point of ligation, for the reason that a free communication will be established through the vertebral arteries, which will permit of a flow of blood into the internal carotid, past the angle of bifurcation in the common carotid, and thus on into the external carotid, and to the place of injury. The practical point, then, is, when branches of either the external or internal carotid arteries become wounded in such situations as will require the ligation of the main vessel, it becomes necessary to ligate both external and internal carotids upon both the sides wounded, or both internal and common carotid arteries. The application

of ligature can be most easily effected upon the common and internal carotids, on account of the numerous branches given off by the external carotid, and the difficulty incident to reaching the main trunk of the vessel.

The wound in the neck was not entirely healed, and that might lead to suspicion that the patient was not entirely out of danger; for there was pulsation yet remaining all along the sterno-mastoid muscle, and why it existed was a point of interest.

CASES OF HEMIPLEGIA.

The patient was 46 years of age, married, and a tanner by occupation. Family history good, no syphilitic taint. Has been suffering from hemiplegia for two years. Loss of motion and impairment of sensation upon the right side, but there was no aphasia, as might be expected, perhaps, when the lesion producing the hemiplegia occurs in the left portion of the brain. This patient was suffering from incontinence of urine. *Belladonna* serves a very good purpose in many cases of incontinence of urine from paralysis, and is worthy of a trial in these distressing cases.

Another case of hemiplegia was noticed which presented some features of interest. The patient was a young man, 20 years of age, who gave an imperfect history, for the reason that he gave an imperfect expression to his thoughts. A kind of forgetful aphasia was developed in his case, and the hemiplegia was upon the right side.

Regarding right hemiplegia and aphasia, they are ordinarily associated; but there are cases of left hemiplegia with aphasia. Some of these cases may be explained by the existence of a double lesion, yet there are well-established cases of left hemiplegia alone with aphasia. Another point of inquiry in the case was, whether the hemiplegia was due to cerebral hemorrhage or to embolism. There was no cardiac murmur; but embolism may occur independent of cardiac murmur, although the existence of a cardiac murmur would be strong evidence that the hemiplegia was due to embolism, and not to cerebral hemorrhage.

Without renal disease, and without hypertrophy of left heart, cerebral hemorrhage in a person of his age would be rare. Both these conditions were absent. Yet the great disturbance of his intellectual faculties might lead to the inference that a cerebral hemorrhage of considerable size had taken place. The boy was in a stertorous condition for four days. When apoplexy occurs in a person over 40 years of age, an atheromatous condition of the arteries may be inferred; hence the liability of the repetition of apoplectic seizures in a person in whom it has once taken place.

When apoplexy occurs in a young person the recovery is, as a rule, more rapid than in older persons—say persons above 40 years of age. The aphasia is not generally completely restored.

Recovery from the effects of embolism, if an important vessel has become obstructed, quite commonly reaches a certain point and then ceases; that is, complete recovery from the effect of embolism is not so general as complete recovery from cerebral hemorrhage, especially in young persons. Positive diagnosis in this case is probably unsafe.

The treatment adopted consisted chiefly of nourishment, and the use of electricity to maintain muscular contractility.

AN IMPORTANT POINT IN THE HISTORY OF A CASE.

The patient gave the following history: M—, at 28, and well built, had been sick during the last six weeks. First had pain in the left side six weeks

ago, but no regular chill at any time. Previous to that time had had cough for a year and a half; had lost flesh at times, but was able to work, and felt strong and well until he got a wetting, and that was followed by the pain in the side, of a "catching" character, and this had continued more or less up to date—Nov. 4th, 1873. Since his admission to the hospital the temperature had risen to 102°.

Upon physical examination, but very little difference by inspection was recognized in the two sides. There was diminished expansion upon both sides. Vocal fremitus was most marked upon right side. There was dullness upon percussion on the left side posteriorly, above, and flatness at the lower portion of the left pleural cavity. Exaggerated resonance upon right side. There were crackling sounds heard most distinctly in inspiration, and somewhat in expiration, all over the left posterior region. Listening directly beneath the scapula, which can be reached by placing the hand of the patient upon the opposite shoulder, certain sounds were heard. It is believed by some of our best observers that evidences of softening, which may follow a croupous or catarrhal pneumonia, can be earliest obtained at that point—directly under the scapula. In this case there were heard either mucous râles or fine gurgles, and this was the *important question* to be determined. The sounds were high pitched. If these sounds were mucous râles, the prognosis was not necessarily unfavorable; whereas, if they were gurgles, the prognosis, although it might not be absolutely unfavorable, yet would be placed upon an entirely different basis. There were no physical signs developed by examination of anterior region of chest which would assist in determining this question. There was only dullness in right infraclavicular region accompanied with broncho-vesicular respiration, which might be suggestive. The development of phthisis in connection with a pleurisy, in the form of a broncho-pneumonia, developing itself after the pleurisy has become established, is not uncommon. The rise in temperature is a suspicious symptom, and is to be carefully watched. The rise in temperature, which the patient now has, has been developed within a few days, and whether it depends upon an increase of lung consolidation, or the advent of softening in previously consolidated lung-tissue, is the *important point* in the history of the case. The treatment instituted in such a case consists in the administration of cod-liver oil, if well borne, good air, nourishing diet, large doses of quinine to subdue the fever, and some counter-irritation over that portion of the chest which is the suspected seat of the broncho-pneumonia. The subsequent history of the case was a rapid development of phthisical symptoms.

PERI- AND ENDO-CARDITIS AND ACUTE ARTICULAR RHEUMATISM.

The patient who was the subject of this attack was a sailor, æt. 23. Intemperate. Always healthy. The rheumatic attack made its appearance in the usual manner, and the cardiac complications were developed as they are ordinarily. The noticeable feature in the case was that both pericarditis and endocarditis were developed while the patient was under the *full influence* of the alkaline treatment, and the urine was *alkaline* at the time of the occurrence of the complications. The development of a mitral systolic murmur during the progress of the rheumatism is regarded as the only trustworthy evidence of the accession of endocarditis. This murmur is also called *systolic, heard loudest at the apex*. The treatment which the patient had received consisted of

R. Potass. acetat.	ss.
Liq. ammon. acetatis.	ij.
Sode bicarb.	i.
M.	
R. Acid. citricum	ʒ ij.
Aque.	ʒi.
M.	

These two mixtures were consumed in twenty-four hours as effervescing draughts.

Anodyne mixture, consisting of

R. Sol. morph (Mg.)	ʒ iss.
Fl. ext. bell.	ʒ ss.
Aqua cinnamomi	ʒ ij.
M.	

Teaspoonful p. r. n.

Another feature of the case was the delirium which was present.

This might be significant of two things.

It might be due to a form of rheumatic meningitis, which differs from ordinary meningitis in not being so marked in regard to local symptoms; or it might be delirium incident to the intense fever, and the latter was probably the correct interpretation, for his temperature had been as high as 104°, with respiration at 36°. This morning, Dec. 4th, his urine is alkaline, and he is very quiet, and is placed upon quinine in five-grain doses every four hours. Good nourishment, perfect quiet in bed, and chest covered with flannel. The amount of fluid effusion is not yet very abundant in the pericardium.

WALKING PNEUMONIA.

It occasionally happens that pneumonia is developed, and will run its entire course, terminating favorably, and cause but little disturbance in the system. Such a case was that of M—, laborer, and admitted to the hospital Dec. 9, 1873. He had usually enjoyed good health; intemperate. Upon admission he had the following symptoms: Anorexia, fetid breath, and irregular bowels. Urine negative. Temperature 102½°. Pulse 120; respiration 34. His present illness had been eight days in duration when admitted, and when first attacked had a chill, flashes of heat and sensations of cold, and pain in side. He had not been in bed before his admission, nor had he been in bed since his admission, except at night. Physical examination revealed dullness in the left infrascapular region, sub-crepitant râle diffused over the extent of dullness, and vocal resonance increased.

Doubtless the patient is passing through the resolving stage of pneumonia; but he has had no characteristic expectoration, and but trifling cough. This does not, however, militate against pneumonia, because such cases do occur. He has been receiving sulphate of quinine, five grains, every four hours, and to-day, two days after his admission, his temperature is 110; pulse 106; respiration 36; and his appetite is improving. Such pneumonias have also been called "*sneaking pneumonia*."

SINGLE WRISTDROP.

This belongs to a class of cases which may give some trouble in finding the cause for the paralysis. The occurrence of this particular form of paralysis, as far as the "wristdrop element" is concerned, at once might reasonably suggest the presence of lead in the system as the offender. Lead in the system gives rise to paralysis of the extensors in both upper and lower extremities. It is claimed that when the paralysis is bilateral, and wristdrop is developed, it may be regard-

ed as positive evidence that the paralysis is due to lead.

When these symptoms are well developed, the source of the poison is sometimes very obscure. It is always well to test the urine for lead, especially in these obscure cases, because by so doing the presence or absence of it may be determined, whether its source can be found or not. The patient who was the subject of the single wristdrop was addicted to the use of strong drinks, and five weeks ago the drinks got the better of him, and he brought up with single wristdrop resulting from sleeping upon his arm for several hours. In such a case, frictions, electricity, passive and active exercise are the restorative measures to be employed.

HYPODERMICS OF WHISKEY.

A man was brought into the wards of surgery of which Dr. Figueiro is house-surgeon, having a crushed foot and ankle, as the result of being traversed by a railroad car-wheel. Previous to his admission the patient had lost a great quantity of blood, and it was feared that he could never be rallied to the amputating point. Among the measures adopted for his restoration were hypodermic injections of whiskey, and these proved very efficient, not only for their immediate assistance in obtaining the stimulation of the alcohol, but they seemed to tide the man over a point at which his stomach had become very irritable and rejected whatever was put into it. An ordinary dose administered in this manner is from fifteen to thirty drops. This man's pulse was raised sufficient to warrant amputation of the leg, which was done, after applying Esmarch's apparatus for arresting hemorrhage. The apparatus was particularly adapted to this case, for the reason that it was desirable to retain all the blood possible, for the loss had already been too great. No blood was lost, and but four turns were given to the rubber-cord.

Correspondence.

THE INVENTION OF TUNNELLED URETHRAL INSTRUMENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I regret being obliged to ask for more space in your columns, but hope it will be for the last time on this topic. I had no intention of entering into a controversy about these instruments, for I had already said all that was necessary upon the subject in my various papers and in my book; but after reading the injurious pseudonymous attack in *The Lancet*, I thought I was called upon to defend my assailed rights.

Dr. Van Buren's communication, when stripped of its personalities and invective, contains certain specific allegations, and new issues, which I am forced to notice. To the remainder, which was entirely uncalled for, I shall pay no attention further than to say that his assertions are unsupported by proofs, and that he has utterly failed to answer my letters of October 1st and December 15th, 1873, published in *THE MEDICAL RECORD*, while he has endeavored to "perplex the order and simplicity of facts, to confound dates, and to wander from the main question."

Ingratitude, which the Doctor urges against me, has nothing whatever to do with this question, even though I were guilty of that "lack of virtue." I was a devoted friend to him, and believed he was the same to me, but finding myself deceived, I, not Dr. Van Buren, "gradually broke off our intimate

relations." I never was the Doctor's partner, and always denied that—outside of the Medical College—I had any connection with him other than being simply his assistant when he required assistance.

He speaks, in his letter, of having called a certain operation "external perineal urethrotomy;" but his friend, Dr. Bumstead, to whom he had applied to give publicity to his claims, and whom he acknowledges to have written most judiciously, says, at page 294 of the third edition of his book, "Recently, Professor J. W. S. Gouley, M.D., in a valuable article which appeared in the *New York Medical Journal*, August, 1869, has adopted the name of 'external perineal urethrotomy,' which certainly defines the operation in question better than any other term." Doctor Bumstead never would have mentioned my name in this connection, if the term had belonged to Dr. Van Buren.

Neither in his published lectures nor his paper of 1868 does Dr. Van Buren use the term external perineal urethrotomy; he speaks of "perineal urethrotomy," which belongs to Civiale, but has never prefixed the word external. To-day, January 26th, 1874, in consulting Dr. Stilling's book on stricture, etc., published at Cassel, in 1870, I find in his bibliography the name of Dr. Félix Bron, of Lyons, who, according to Dr. Stilling, in 1863, used the expression, "*urétronomie externe périnéale*." This clearly proves that the term belongs neither to Dr. Van Buren nor to myself.

Dr. Van Buren does not say a word, in the writings referred to above, about "bridging the end of the staff." It was myself that bridged the end of the staff, as I have shown in my first and second letters—and my statements are attested by the surgical cutlers, and by surgeons of the highest repute in the land.

He says he has in his possession these tunnelled instruments, "subject to inspection." There are hundreds of practitioners who have tunnelled instruments in their possession, and who, like Dr. Van Buren and myself, have paid for them. The Doctor alleged, through another, that he had used such instruments many years ago, before he knew me, but the name of his cutler is still a mystery. In the face of this he asserts that he proposed in November, 1865, a device which I made in January, 1864.

With regard to the non-retention of the catheter after external perineal urethrotomy, the Doctor is again at fault. I cannot avoid transcribing the following, from one of his published lectures, in which, after giving good reasons for not tying in a catheter, he says: "Besides the case of the boy now before you, which, in regard to this point of treatment, furnishes the most satisfactory evidence. Dr. Gouley, who, as far as my knowledge extends, was the first to adopt this practice, has employed it with equally good results in other cases." (See *THE MEDICAL RECORD*, June 15th, 1866, p. 181.) Dr. Van Buren was, at first, opposed to this practice; he urged, among other things, that it was necessary to leave in the catheter for, at least, forty-eight hours, in order that the urethra might mould itself around the instrument. He did not accept as good the practice of non-retention of the catheter until I had fully demonstrated its utility to him and to others, and he did not carry it into effect until 1867, while I had done it as early as 1860. (See my paper of August, 1869, *New York Medical Journal*.) In his letter of January 15th, 1874, he claimed this for himself. Such contradictory statements require no comments from me.

He is as inaccurate regarding conical sounds as he has been in nearly everything else he has said, and I shall take no space to discuss this question.

He is quite as inaccurate in his assertions about the

modification of Sir Henry Thompson's instrument. He had nothing whatever to do with this. The modification was made entirely by myself, and he did not even see the modified instrument until after I had used it. This is not altogether a question of veracity between us, for I have already given my proofs, while he has furnished none.

What he now says about my book, which he before praised so highly, is as inconsistent as it is inaccurate. In this book I have ignored no one who had ever contributed anything useful in the branch of which it treats; and among the many authors—American and foreign—whom I have cited, Dr. Van Buren's name appears in its proper place, with all the prominence it deserves. He says he recognizes his "teaching" in this book. I am not aware that he ever had any original views on the subject. His "teaching," in diseases of the urinary organs, is to be found in the standard works, in none of which, however, is there anything that he can justly claim as his own.

I have confined myself, in this letter, entirely to questions of fact, and would not have deemed it necessary to reiterate what I had already said upon the subject, were it not for the disingenuous assertions of Dr. Van Buren, and the side issues taken by him.

I have the honor to be,

Very respectfully, your obedient servant,

J. W. S. GOSLEY.

Progress of Medical Science.

THE INNER LIFE IN PLANTS.—A most valuable discovery was communicated to the Royal Society, at one of its recent meetings, by Prof. J. Burdon Sanderson, regarding the electrical phenomenon which accompany the irritation of certain leaves. It is a well-established fact that electric currents occur in animal muscle, but it has not hitherto been demonstrated that a similar principle pervades the vegetable world. The doctrine of protoplasm and the agreement as to the cause of contraction in all living substances is much affected by this new discovery; and it is not at all unlikely that the contractile substance, both in muscle and in vegetable tissue, may be proved to be protoplasm. At any rate, it throws considerable light upon the nature of contractile substances in general. Prof. Sanderson was led to investigate in this direction from a conversation had with Mr. Darwin. The experiments are simple, and can easily be repeated and verified. The opposite ends of a living leaf of dicotyl are placed on non-polarizable and connected electrodes. A reflecting galvanometer of high resistance is inserted in the circuit, and a deflexion of the magnetic needle results, plainly indicating that a current is passing from the proximal to the distal end of the leaf. If, instead of the leaf, the leaf-stalk is placed on the electrodes, a current is again observed, but running in an opposite direction. If, the leaf being so placed on the electrodes that the normal leaf-current is indicated by a deflection leftwards, a fly is allowed to creep into it, it is observed that the moment the fly reaches the interior (so as to touch the sensitive hairs on the upper surface of the lamina) the needle swings to the right, the leaf at the same time closing on the fly. The fly having been caught, does not remain quiet in the leaf; each time it moves the needle swings again to the

right, always coming to rest in a position somewhat further to the left than before, and then slowly resuming its previous position. The same series of phenomena present themselves if the sensitive hairs of a still expanded leaf are touched with a camel's-hair pencil. In experimenting on an open leaf there is this peculiarity, that no effect is produced unless an interval of from ten to twenty seconds has elapsed since the preceding irritation. After each stimulation the leaf is, as it were, exhausted, and requires time for a process of restitution. This is a characteristic point, showing that, similar though the process be in both animal and vegetable matter, it is not exactly the same. The period of latent stimulation is one-hundredth of a second in muscle, but one-third in the plant—that is, if the expression may be used, the leaf takes thirty times as long as the muscle to consider before it will allow itself to be stimulated to renewed action.—*Med. Press and Circular.*

OPERATION BY THE ELASTIC THREAD.—*The British Medical Journal* says that on the 21st of November Sir Henry Thompson demonstrated, for the first time in England, a surgical procedure which has been practised for some time past by Prof. Dittel, of Vienna. Some time ago Prof. Dittel discovered by accident the power of an elastic thread in dividing tissues, and at once began to reduce the idea to practice. He first applied it to a case of nevus of the scalp of a child; then finding that the plan quite answered his expectations, he applied it to the removal of the testicle, penis, etc., and finally to the amputation of limbs. It is not understood, however, that he proposes to employ the method in the case of the larger amputations.

The time required for the completion of an operation varies according to the amount and density of the tissues which have to be divided, e.g., for the separation of the mamma from eight to twelve days are required.

Among the operations for which it is admirably adapted may be especially mentioned *fiatula in ano*. One end of the India-rubber thread is passed, in the eye of a probe, up the sinus into the bowel, then caught, brought out at the anus, and tied; it cuts out in a few days.

The patient on whom Sir Henry Thompson operated was a stout, middle-aged woman, who was suffering from an ulcerating fibro-cystic tumor (cystic sarcoma) of the right breast. She had a lump in the breast for twenty years, but it caused her little inconvenience till two years ago, when it began to enlarge rapidly, and finally the skin over it gave way. At the time of the operation the tumor was of the size of a large orange, and somewhat pendulous, the breast itself being wasted; it was crowned by a large, sloughy, fungoid ulcer. The ligature used was tubular, about one-twelfth of an inch in diameter, the calibre of the tube being about one-third of this. A large nevus needle was threaded with this and a piece of twine, and passed under the base of the tumor. The elastic was then cut, the needle withdrawn, and the halves of the pedicle tied separately. The twine was passed with the rubber-tube, in order that a second tube might be introduced in case the first should break. The patient complained of pain, apparently not very severe, for about twenty minutes after she recovered from the chloroform. Dr. Dittel's paper in the *Allg. Wiener Med. Zeitung*, 1873, contains very full details of the method.

TRACHOMA TREATED BY GONORRHOEAL INOCULATION.—Dr. Léon Brière reports in the *Bulletin Générale de Thérap.*, Sept. 15, 1873, four hundred and four

cases, from various sources, of pannus treated by the inoculation of blennorrhagic virus, derived either from the ophthalmia of the new-born, or from urethral or vaginal blennorrhagia. To these he adds five cases in his own practice. Having quoted, with approval, the conclusion of Roosbreck, who has never seen any grave accident follow so seemingly frightful a plan of treatment, and who observes, "I regard these results as so complete, so marvellous, and so extraordinary, that I do not believe anything more beautiful exists in all ophthalmology" the author sums up in the following indications and contra-indications:

1. Inoculation gives results satisfactory in proportion as the pannus has arrived at a very high degree of development (without incurable complication on the ocular surface).
2. In pannus which is generalized over the whole surface of both cornea, accidents are most rare.
3. Inoculation must never be practised in cases of unilateral pannus, as the most scrupulous care of the sound eye will not save it from contagion.
4. Inoculation is equally contra-indicated where the pannus is partial, and where the cornea presents points.
5. In cases of double pannus, it is preferable to inoculate both eyes at the same time. It is a matter of indifference whether the inoculating matter be taken from an ocular, vaginal, or urethral blennorrhagia. An individual refractory to the influence of one kind may be affected by another virus, seemingly less active. The pus of acute urethral blennorrhagia is more active than that of the chronic disease. The material of inoculation should be picked up with a pair of forceps and deposited upon the palpebral conjunctiva. If its escape be feared, the conjunctiva may be punctured with a lancet or needle. The course of purulent ophthalmia of artificial induction is the same as that of accidental origin. Should the cornea not ulcerate, frequent applications of warm water should be made. Van Roosbreck lets the affection take its own course. Should the cornea exfoliate (intense pain), Warlombert recommends the application of the nitrate of silver, in stick or solution.

A NEW OPERATION FOR CLEFT PALATE.—On the 22d of Nov., Sir William Fergusson (*The Lancet*, Nov. 22), in operating on two patients for the closure of the opening in the hard palate after the cleft in the soft palate had been closed, adopted a modification of a procedure which is intended to increase the chances of success of the operation. Sir William remarked that in the so-called Langenbeck operation—that is, where muco-periosteal flaps are taken from the roof of the mouth and drawn towards the middle line—the proceeding is often unsuccessful, from the fact that after some time the granulations that are thrown out on the upper surfaces of the displaced flaps contract and separate the union that may have taken place between the pared edges of the flaps. It is true, he observed, that some assert that bony matter is deposited on the upper surface, and that this diminishes the size of the aperture in the osseous palate. But, in demurring to this, Sir William said he thought it was hardly possible to strip off healthy periosteum from the subjacent bone. He proposed therefore, instead, that in addition to making the ordinary incisions for the flaps, the hard palate should be split on each side of the opening with some sharp cutting instrument, and that the two pieces of bone should be pressed towards the middle line, and the pared edges of the soft tissues then be brought together; by this means the apertures opening would be closed, but two lateral apertures would be formed. But inasmuch as the two lateral

openings would be but half the size of the original central one, and as there would be more likelihood of the fractured edges of bone throwing out osseous material for its repair, it was hoped that the prospect of a successful issue would be greatly enhanced.

ON THE IMPORTANCE AND DANGERS OF REST IN PULMONARY CONSUMPTION.—An interesting paper on this subject, by Dr. Berkart, has drawn from Dr. Horace Dobell a communication on this topic, which appears in *The British Med. Jour.* of Nov. 22. He says: "The rules for the cautious application of localized rest in lung-diseases which I recommended, as dictated by a consideration of the nature of tuberculosis, and justified by the results of my own practice, are as follows:

- "1. If one lung, or a portion of one lung, or a portion of each lung, has become diseased, under circumstances which make it certain that there is no constitutional cause of lung-disease, then it is safe to secure localized rest for the diseased part, and to throw the extra work upon the sound parts; but even then it is necessary to be cautious that the extent of the lung so rested is not too large in proportion to the extent of sound lung upon which the extra work is thrown. If there is any question about this, rest of the whole body must be secured in addition to the localized rest of lung, so as to save the sound lung from as much work as possible.

- "2. If there is a constitutional cause of lung-disease, but only a small area of lung at present suffering, and that in the upper lobes, while there is a capacious chest with large areas of lung in the lower portions quite sound and insufficiently used, then it is safe to secure localized rest for both upper lobes, and to make the lower portions do a fairer proportion of the work; but even under these circumstances the respirations should be kept at as low a point as practicable.

- "3. If a portion of lung has become disintegrated, under the influence of constitutional causes, and remains obstinately unhealed after all constitutional symptoms have been arrested, and, for some time past, no other portions of lung have shown a tendency to yield, then I think it is quite safe to secure localized rest for the disintegrated portion, so as to give it a fairer chance for healing; while an amount of air and exercise may be allowed to the patient, for the purpose of improving his reparative powers, which could not have been permitted while the damaged lung was exposed to the same amount of action as the sound parts. But even here the utmost caution is required not to carry the exercise beyond a very limited amount.

- "4. If the constitutional tendency to lung-disease—the abnormal physiological state—is strong, and signs of impending mischief in the lungs are scattered, no localized rest should be attempted, but every means should be brought to bear upon the important object of maintaining respiration at its lowest point consistent with life and nutrition, until the constitutional tendency has become passive and the local symptoms have been removed.

"In conclusion, to prevent misapprehension on so vital a point, let me remind my readers that, in urging 'the importance of rest in consumption,' I am referring to cases in which the lungs are already damaged, or in which the constitutional disease has declared itself in sufficient force to render tubercularization imminent. If the symptoms are only what are commonly called premonitory, that is, if they are those of commencing tuberculosis, and no reason or sign is discoverable which justifies the suspicion that tubercularization has commenced; if a sufficiency of fat remains without calling upon the albumenoid tissues, the principles of treatment are quite opposite to those detailed."

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, February 16, 1874.

A MEDICAL CENTRE IN NEW YORK.

WHETHER it be a pleasant thing to admit or no, the Medical Society of New York is still in the process of crystallization. Our professional position is not yet fully established, and consequently we have not all the resources for the cultivation of the socialities and amenities that pertain to a refined professional association. We are still young people, of respectable and even distinguished ancestry, who have just set up for themselves—only fairly begun life. Our medical colleges—and whatever may be said about them they are the institutions that above all others give tone to our medical society—are no more to be compared to the schools for medical instruction of Great Britain, France, and Germany, than are the colleges of our border States to be likened to Harvard, Yale, or Princeton.

Our societies, if we may except one, the Pathological, spend their time chiefly in discussing questions that have been raised on the other side of the Atlantic, or in presenting *résumés* of themes that have undergone original investigation in Germany and England. Our books, except so far as they relate to clinical investigations, in which our work may be compared with that of any other country, are for the most part fluent and graceful compilations. We are not saying these rather unpleasant things at all in the way of reproach, for we are of those who believe that the medical profession of the United States is doing about the best it can under the heavy odds of imperfect resources in the way of libraries, chairs for scientific work, and a vicious system of voluntary medical colleges. By the latter we mean colleges that are simply schools, of which the teachers are the owners, and the final judges of the right to practise. We are not entirely to blame even for the bad system of education. Necessities know no law, and the necessities of a new and vast country require a less rig-

orous standard for the average practitioner than do the wants of the over-populated Old World, where doctors are not needed in such numbers and in such urgency as with us. While we acknowledge these deficiencies, and speak plainly of them, we yield to none in our admiration for the sterling clinical value and the operative skill of our medicine and surgery.

But the time has come when we must change all this, and ask no odds of any country in the struggle for scientific culture. Already Chinese, Japanese, Greeks, and Armenians are choosing New York as a place for medical instruction, in preference to London and Vienna, and they will soon be followed by the more cultivated races. We must begin to enlarge our resources, and to broaden our culture, in order to adapt ourselves to a new position of larger influence, which, if we act wisely, will be upon us in a decade or two. We cannot now discuss the necessity of changes in our system of instruction; we have already done so in the columns of *THE RECORD*, and we hope to take up the subject again, as there may be occasion. The want which we now wish to urge upon the profession of New York in particular, as one that imperatively demands to be filled, is that of a common centre, to which the profession can gather; where they can found a library worthy of the age; where they can meet in social or scientific conclave, or to welcome distinguished medical brethren who may honor New York by their presence. In fact, we need for our city a combination, if such a thing be possible, of a club and a university hall. We need a home for the profession, under whose roof all the medical societies of the city may find a place, and in whose library, laboratory, and museum our professional friends from other cities and from our country-towns may pass hours of profitable and pleasant investigation. The Medical Library and Journal Association has struggled vigorously to give us the *club* part of such a hall; but its impecuniosity has only sufficed to furnish a tolerable library, and a good collection of journals in rather an uninviting room.

The most pretentious of our societies—the New York Academy of Medicine—a society which calls its members *fellows*, which publishes transactions at irregular intervals, and which is said to have a library in the garret of one of its members, has been engaged during the last ten or dozen years in picking up subscriptions for the purpose of erecting a building, of which the glory of name and ownership shall belong to itself; while the County Medical and Pathological Societies, with the Journal Association, and a host of smaller and special organizations, such as the Obstetrical and Ophthalmological, may, if they choose, get admission as occupants in a strictly subordinate way. Now this plan might be feasible if the Academy of Medicine had shown in the past, or was showing in the present, such a pre-eminence in good scientific work as would entitle it to gather all our medical brood under her

not over-expansive wings. But as matters are now, it is idle to think that the active men in the County and Pathological Societies, who are many of them members of the Academy also, will consent to give up their money to the management of what, after all, is but a sister organization, with no higher claims to respect than themselves. As a sample of what the Academy is capable of doing in the way of creating enthusiasm and getting money, we may adduce its late social gathering, held under the auspices of a select committee. After a supper which certainly was not extravagant in price, but which will probably be remembered longer than the committee of arrangements could desire, the Academy proceeded to bring forth the speakers who were to furnish the sinews of war. These speeches were begun in exquisite taste by the distinguished President of the Society; but they were continued in such a prolix way by an estimable, if not eminent, member of the bar, that the audience, overcome by the supper and the speech, soon thinned out, while those who remained did not seem to have the slightest idea of subscribing one cent to the fund, which was said by the chairman of the subscription committee to be about twenty-four thousand dollars.

We are convinced that the Academy of Medicine has no such record in the years of its honorable but not brilliant existence, that it will induce the New York profession to give to it the exclusive management of a common medicine centre. If, however, the Academy will approach the profession in another way, we believe that our great want of a hall, or series of halls, may be filled. Let the Academy gracefully yield the idea that this work can be done by it alone, and appoint a committee to co-operate with like committees from the other leading societies. Let the joint committee thus formed seek to raise the money to buy, or build, or even lease a building, to be called, for example, although the name is but of small account, New York Medical Association. This hall should be managed by a board of trustees made up of the officers of the Academy, the County Medical and the Pathological Societies. The additional twenty or thirty thousand dollars, needed to secure the control of such a building, would even in panic times soon be forthcoming, under a combined and vigorous effort; while the successful inauguration of such an enterprise would be but the beginning of a series of steps necessary to make New York a great medical metropolis.

If it is found impossible to raise the whole of the additional amount, it would be better to imitate the Bar Association and hire a house, than to leave the money already raised to slowly increase for the benefit of a generation of the profession not yet on the stage. We are doing enough for the future generations, as a nation, in paying off the debt of war, all the dangers of which we have borne, to be relieved from such obligations as one of putting out our money at interest

to provide a place of meeting for the coming medical man.

THE MEETING OF THE STATE MEDICAL SOCIETY.

THE meeting of the State Society was, as usual, a success. A larger number of delegates and members than usual were present, and the interest manifested in the proceedings was in keeping with the purpose of men gathered from every part of the State for professional benefit and encouragement. The choice of President was a singularly unanimous one, and reflected credit alike upon the Society and upon the one singled out to represent it.

The address of the retiring President was a model in its way, and was one of the memorable features of the meeting. The masterly handling of an old subject in such a comparatively new light proved the cultivated scholar as well as the ripe thinker.

Dr. KENDALL brought up his former resolution in regard to the choice of members of the nominating committee by the delegates from the respective districts, but apart from inviting a pretty general discussion nothing was accomplished. The plan strikes us in the main as a good one, but for the present we must be satisfied with the old way. So far the appointing powers have been judicious, and from the discrimination of the incoming President, his knowledge of the system, and his thorough acquaintance with the members, we have every reason to expect the strictest impartiality in this as in all the other administrations of the duties of his responsible office.

The new departure concerning the publication of the Transactions is one which will be watched by every one interested in the prosperity of the organization, and it is to be hoped that the results will equal the expectations of the most sanguine. The resolutions concerning the army staff rank were well put, and commanded, as they should, the unqualified indorsement of the Society.

BELLEVUE AND CHARITY HOSPITAL APPOINTMENTS.

THE following has been passed recently by the Commissioners of Charities and Correction, and speaks for itself:

Resolved, That it is the sense of this Board, that it is inexpedient for any visiting Physician or visiting Surgeon connected with the Bellevue or Charity Hospital to hold more than one position in either of the same, and that such visiting Physician or visiting Surgeon that is now holding more than one of the positions in the two hospitals named, be respectfully requested to elect in which of the said hospitals they desire to continue to hold their positions.

This resolution to take effect on 1st March next, and copies ordered to be sent to the Medical Board.

This will create four vacancies, which we hope to see filled by gentlemen who have no appointment in any other hospital.

Medical Society of the State of New York.

ANNUAL SESSION, HELD IN ALBANY
FEBRUARY 3, 4, AND 5, 1874.

FIRST DAY—MORNING SESSION.

THE Society convened in the Common Council Chamber, and was called to order at 11 A.M. by the President, Dr. E. M. MOORE, of Rochester.

Prayer was offered by Rev. Dr. James.

The Inaugural Address was then delivered, and, upon motion of Dr. J. G. Adams, of New York, was referred to a Committee of Three, for the purpose of taking into consideration the suggestions and recommendations contained therein, and report to the Society. The amendment of the fundamental laws of the Society in reference to non-legislation in medicine, formed the general subject of the address.

The Chair then announced the following Committees:—

Ethics—Drs. Thomas Hun, E. R. Squibb, and D. B. St. John Roosa.

Arrangements and Reception—Drs. J. V. P. Quackenbush, Wm. H. Bailey, and W. S. Ely.

Credentials—Drs. Chas. E. Rider, Robt. Newman, and G. L. Halsey.

Business Committee—Drs. S. O. Vanderpoel, W. D. Didama, and Harvey Jewett.

The SECRETARY read the following report of Dr. Samuel Hart, of Brooklyn, as delegate to the Rhode Island State Medical Society:

To the Medical Society of the State of New York:

Agreeable to your appointment, I attended the annual meeting of the Medical Society of the State of Rhode Island, as your delegate, on the 11th of June last. I was kindly received. It was a meeting for the annual business of the Society, which, being accomplished, the Society dined together and adjourned.

MODE OF TRANSMISSION OF YELLOW FEVER.

There being no further business by way of reports of committees and introduction of resolutions—

DR. S. O. VANDERPOEL read a paper entitled, "Mode of Transmission of Yellow Fever and Cholera as relating to Quarantine." The Doctor gave a brief outline of the symptoms and course of yellow fever, and regards those cases which are mild in their attack as being as severe in their results as the grave cases. It was to be termed an exotic disease. Once introduced, it may be developed and propagated in this country, but never originated here. The disease is of paludal origin, and is sustained by decaying vegetation, filth, etc.

There is no analogy between yellow fever and malarial fever, although both are due to what are termed miasm. One is transmissible, and the other is not.

Yellow fever is believed never to occur at an altitude of more than 500 feet above the level of the sea. It is chiefly transported from place to place by transmission of the germs by means of ships.

The opinion of physicians is unanimous that it is not spontaneously generated in ships. The ship, however, may be a powerful agent for the retention of the germs. Even the remaining of the ship in cold latitudes for some length of time is not sufficient to destroy these germs.

It is a living, vital germ, existing on ship-board wherever a favorable nidus may be situated, and filth is a powerful and common agent in assisting its detention. The holds of vessels are the most favorite situations

for germs of the disease. Water of the bilge is also a favorite nidus for the retention of the germs. It may also be transmitted by clothing.

It is, however, not directly contagious from person to person. In every case where the disease was developed last season it was immediately traced to transmission by way of ships.

In cholera, the cure is entirely different, and that disease may be said to be endogenous, while yellow fever may be termed exogenous.

Cholera is also of paludal origin. It is transmissible and also contagious. It may be conveyed wherever routes of human intercourse exist, whether by land or by sea.

It is transmissible from the sick to the healthy by means of a material poison, and is capable of being conveyed to a distance. Neither great moisture nor dry air are essential to the transmission of the disease.

The essential difference between the two diseases is apparent.

As regards yellow fever, it is now regarded that five days are sufficient, if proper measures are introduced to secure thorough cleanliness and disinfection, to wipe the disease entirely out, and thoroughly eradicate the germs of the disease from ships; therefore if five days are allowed to elapse between leaving a port where yellow fever is prevailing, and arrival at a port where the disease is not prevailing, it is sufficient to prevent its spread by means of ships, if proper measures are resorted to during the voyage to give all the benefit of ventilation and disinfection and proper cleanliness, and in this manner no hindrance to commerce becomes necessitated. With regard to cholera, it is communicated in connection with the characteristic discharges from the alimentary canal; by soiling the hands, clothing, etc.; by throwing the discharges into sewers; by percolation through the soil, and communication with water-courses; by rising of watery vapor into the air; and by the discharges being dried and rendered into an impalpable powder ready for easy transmission. Choleraic diarrhea is equally potent to communicate the disease as discharges from completely developed cholera.

Fresh cholera stools are harmless; it requires a certain amount of decomposition to render them pernicious; and a certain additional amount of decomposition renders them again harmless.

The period of incubation is probably not more than ten days. No arbitrary rules can be laid down with regard to the detention of vessels arriving having cholera on board, or which have had cholera on board at any time during the voyage. Each vessel must be regarded by itself, and its forwarding or detention is to be determined by the condition of the vessel, the isolation of the cases which have occurred, and the means which have been placed in operation for the arrest of the disease at its first appearance and subsequent progress.

The first endeavor should be to stifle the disease in its very earliest manifestations. When proper sanitary measures are adopted, the disease may be held within proper limits without materially restricting the commerce of our country.

DR. QUACKENBUSH introduced Dr. Wheeler, of Boston, as delegate from the Massachusetts State Medical Society.

DR. WHEELER responded with appropriate remarks. DR. SNOW, from Maine, was also introduced, and responded by returning thanks for his reception.

Drs. Eugene Beach, Gloversville, Fulton Co.; J. W. S. Gouley, of New York; L. D. Woodruff, of New

York; Fred. Geare, of St. Lawrence Co.; George M. Beard, of New York; G. T. Stephens, of Albany, were named as invited guests.

DR. VANDERPOEL, from the Business Committee, announced the reading of a paper by Dr. Wheeler, of Chelsea, Mass., upon the subject of fibroid tumor of the uterus.

DR. SQUIBB introduced a resolution, requesting that the paper read by Dr. Vanderpoel before the Academy of Medicine of New York, be annexed to the paper just read by him, in order that the two might appear in their proper connection in the published Transactions.

The paper of Dr. Vanderpoel was then discussed by Drs. A. N. B. J. E. Krackowizer, B. F. Sherman, E. S. Wolff, and J. C. Hutchinson. In the course of the discussion the question arose with reference to the use of the terms infectious and contagious, as used in connection with cholera in Dr. Vanderpoel's paper. Dr. Vanderpoel explained that he had used the term contagion in the sense of a general term as applied to the disease being communicated from person to person, whether the real nature of the poison is infectious, or whether it is necessary that the material constituting the poison shall pass through some secondary change. There may be some periods in the course of the disease where the word infection perhaps would better express the exact condition present than the word contagion. He did not wish to be understood that he regarded cholera as being contagious. He wished to use the term in the sense in which it is used by Frascator.

Discussion was then closed.

DR. VANDERPOEL, from the Business Committee, reported the presentation of a paper upon "The Use of Sulphate of Quinine in Epistaxis," and also a paper upon "The Use of Bromide of Potassium in the Nausea and Vomiting of Pregnancy;" both papers being presented by Dr. S. Caro, of New York.

The papers were referred to the Committee on Publication.

EXTRA-UTERINE FIBROMA.

DR. WHEELER now proceeded to read his paper, and illustrated his case by the presentation of photographs.

His case was one of extra-uterine fibroma. It was of ten years' growth, and weighed 52 pounds. Death was caused by sudden attack of hemorrhage from the cavity of the uterus. There was no disturbance of the menstrual function throughout the entire progress of the case. There was no change in the length of the cavity of the organ. No hemorrhagia, because the mucous membrane of the uterus was not invaded until the very last. She was the mother of three healthy children; the youngest was six years old. She passed the climactic period without the development of any unusual symptoms. Hemorrhage at last came without apparent cause, was profuse, and caused death within three days. There was no edema of lower extremities, nor ascites. The tumor, at post-mortem, was found to be attached by a pedicle to the anterior surface of the uterus. The pedicle was about two inches in diameter, and, passing through the parietes of the uterus, produced the source of hemorrhage which caused the death of the patient.

DR. QUACKENBUSH announced the names of the following gentlemen as invited guests:—Drs. John C. Sill, H. A. Long, and Asahel Perry, of Washington Co.; Drs. Lewi, Jas. S. Bailey, Dezonche, F. C. Corliss, and Ferguson, of Albany; Dr. Henry Quackenbush, of New York City; Dr. Solomon Sias; Dr. Henry Spurbeck, of Schoharie Co.

DR. VANDERPOEL announced the reception of a paper

from Dr. Wey, of Elmira, upon "Dilatation of the Stomach."

DR. WEY also read a brief paper sent to the Society by Dr. Squire, of Elmira, upon "Vertebrate Prostatic Catheter."

The leading features of the communication were, that the instrument had been so modified as to overcome all difficulty of withdrawing the instrument; that the instrument is perfectly safe if properly constructed, and that no vertebrate catheter should be made of a size less than No. x. The only unfavorable accident is that which may attend breaking of the joints of the instrument.

An Evening Session was voted, and the subject announced for consideration at the evening session was the report of the Committee upon Hygiene, upon "Defective Drainage."

Society adjourned, to meet again at 3 P.M.

AFTERNOON SESSION—Feb. 3, 1874.

Society called to order by the President at 3 P.M.

APPLICATION OF HYDROSTATIC LAWS TO THERAPEUTICS.

The first paper read was upon "The Application of Hydrostatic Laws to Therapeutics," by Dr. Chamberlain, of New York. The paper was a description of apparatus to be employed for the application of water, either hot or cold, in the treatment of disease. The apparatus consisted of rubber tubing, with a nozzle and stopcock attached, so arranged that it will conduct fluid from a vessel above upon an object below its level. The apparatus can be used for the treatment of almost all forms of disease and conditions of system which will admit of the use of this remedial agent in any form. Removal of foreign bodies from the ear; treatment of diseases of the eye; irrigation of the stomach, etc., etc.

A substitute for the aspirator was exhibited, which consisted in a vulcanite syringe with a stopcock attached to its nozzle, and a piece of rubber tubing to which the nozzle can be closely attached by means of a vulcanite piece, and having attached to its other extremity the ordinary aspirating needle.

DR. VANDERPOEL, from the Business Committee, announced the reception of communications from the New York County Medical Society, and the Allegany County Medical Society, which were referred to proper Committees.

CHRONIC INVERSION OF THE UTERUS.

DR. J. P. WHITE, of Buffalo, next read a paper upon "Chronic Inversion of the Uterus." It consisted of the history of two cases of this affection which had been reduced in accordance with the principles published by him in 1856, and subsequently in 1858, and at other times also subsequent to the latter date. No new principles were advanced with regard to the operation. It was believed that the operation is sufficiently established to render confirmatory evidence uninteresting. Dr. White's uterine repository was used in the operation, for a description of which, reference was made to published Transactions of the Society. One of the cases had been in existence for twenty-two years. Eleven cases have now been reduced by the Doctor, varying in duration from immediately after the occurrence of the accident to that of twenty-two years' standing. The Doctor regards it as being absurd to call this procedure a forcible reduction, as has been done by Dr. Barnes. Gentle, elastic pressure upon the fundus is just sufficient to produce equable traction upon the vaginal connections.

Dr. QUACKENBUSH referred to the use of the probe as a means of diagnosis in these cases, and regarded the only proper means for recognizing the existence and situation of the os uteri to consist in digital examination. The os uteri should be first recognized by the touch. He also did not regard the speculum as being of any service in determining the nature of the affection, for the tissues of an inverted uterus will present no different appearance through the speculum than many other tissues. Another remark with regard to the time at which the operation should be performed. He was of the opinion that duration was not an element of consideration with regard to the possibility of reduction; and that it is just as difficult to reduce a uterus that has been inverted five years as it is to reduce one that has been inverted fifteen years. It may perhaps be more easy to reduce an inverted uterus after the climacteric period has been passed, than previous to that period. The Doctor also referred to the terms acute and chronic, but regarded the terms recent and chronic as being more expressive of the true condition of affairs.

Dr. GRAVES, of Coming, remarked that he was unable to draw the line between acute and chronic inversion of the uterus, as referred to by Dr. White. He referred to two cases which he had had, and which he had called acute because they occurred immediately in connection with delivery. He also referred to two other cases which had been of three and five years' standing, and he had called those cases chronic. In all those cases the uterus was restored to its proper position without difficulty, and no untoward symptoms followed the operations.

Dr. WHITE remarked that he would regard those cases as *acute* which occurred previous to the completion of the process of involution; while those cases which occur subsequent to this period he would regard as *chronic*. He also believed that the danger and difficulty of the operation was greater immediately after delivery than when it had been in existence for twenty-two years. Duration was not regarded as having any influence upon the operation other than that just referred to. Dr. White also remarked that he would not regard the speculum as essential in diagnosis, and in his cases was only used to examine the condition of the os subsequent to the operation. He also agreed with Dr. Quackenbush in his remarks, that the sound should not be resorted to generally, but that the chief method of examination should be by means of the finger. Still, if the sound is introduced into the bladder, and the finger into the rectum, the sound may be of great assistance in arriving at a decision whether the uterus is present or not in its proper position. In cases of inversion it simply gives us negative evidence.

The Business Committee announced a paper by Dr. Wm. B. Sprague, of Genesee County, being the annual address read before the County Medical Society, and entitled, "A Plea for old Physic."

Dr. STEVENS, delegate from the Ohio State Medical Society, was introduced. Dr. Stevens was formerly Professor in Miami Medical College, and is now Professor in the University of Syracuse.

Dr. A. HOMER, delegate from the Massachusetts State Medical Society, was also introduced to the Society; also Dr. R. M. FOWLER, delegate from the Connecticut State Medical Society. The delegates responded with appropriate remarks.

Invited guests were announced as follows:

Drs. W. H. Stuart, Norwich, N. Y.; Dr. Cruthers, Albany; C. H. Barbeck, Rens. Co.; J. C. Hutchinson, Rens. Co.; Moreau Morris, New York City; R. W. Barrett, Bennington, Vt.; G. W. Coake, Otego; R. H.

Sabin, Troy; W. H. Rice, Oswego Co.; H. R. Ainsworth, Steuben Co.; W. G. Tucker, Albany.

Dr. ROBERTSON, of Albany, then read a paper upon "Diagnosis of Diseases of the Eye." The subject was considered under two heads, namely, diseases affecting the external portions of the eye and its appendages, and the diseases affecting the internal structures of the eye. A brief outline was given of the various forms of disease, their leading symptoms and peculiarities. The paper gave evidence of reading upon the subject presented, and constituted a sort of epitome of the entire subject.

A paper upon the life and character of the late Alexander H. Stevens, by Dr. J. G. Adams, was presented and referred.

The Committee upon Nomination was announced as follows, by Senatorial Districts:

(1) Dr. C. R. Agnew; (2) Dr. Solomon Van Etten; (3) Dr. G. H. Hubbard; (4) Dr. Z. B. Bridges; (5) Dr. Edwin Hutchinson; (6) Dr. Wm. C. Wey; (7) Dr. E. W. Bottom; (8) Dr. H. W. Dean.

The following resolution was adopted:

Resolved, That the members of the Legislature who are in good standing in their respective County Medical Societies, are invited to attend the deliberations of this body.

A Committee of Three was appointed to carry the resolution into effect.

The Society then adjourned, to meet at 7½ p.m.

EVENING SESSION.

Society called to order at 7½ p.m. by Dr. FRANCIS BURDICK, of Fulton Co.

REPORT FROM THE COMMITTEE ON HYGIENE.

Report from the Committee on Hygiene being the special order of business for the evening, Dr. A. N. Bell, Chairman of the Committee, reported progress as follows:—Every County Medical Society in the State had been communicated with, and asked to send responses to the following questions:

To what extent are the diseases of your county due to insufficient drainage? How many acres of marsh lands have you in your county? Have you intermittent diseases attributable to soil saturation? Are there in your county cases of intermittent fever where surface drainage has been well regulated? What system of drainage is necessary to render your county free from malarial diseases?

The responses have been liberal, having received reports from upwards of fourteen counties.

The reports from several towns were then read. Some of these reports were well digested, and all conveyed the common import that the value of surface drainage cannot be over-estimated in preventing the development of malarial diseases.

The report from the New York County Medical Society was read by Dr. Moreau Morris.

His report was illustrated by maps showing where defective drainage was present in various parts of the city. In several places natural drainage-streams have been constantly obstructed in the construction of public works. Along these old water-courses malarial diseases have been developed, and are chiefly confined to these saturated sections. Drainage is the great prophylaxis for the prevention of malarial diseases. Proper drainage consists in the removal of all surface water which is not necessary to support vegetation.

GEN. VIÉLE, of New York, was then introduced to the Society, and made some remarks upon the subject of hygiene, but particularly as connected with the

subject of drainage in Central Park, New York, and Prospect Park, Brooklyn. The remark was made that saturated soil is the source of more than one-half of the disease in the country. The passage of a law should be secured to compel people to feel that no one man shall flow land or do anything contrary to the interests of his neighbors in a hygienic point of view.

Report was also made from Oneida County by Dr. Samuel G. Woolcott.

Dr. GUERNSEY, of Dutchess County, remarked upon the propriety of securing some system of legislation to protect the people from the suffering which is now imposed upon them in many places, as the result of imperfect drainage, on account of the neglect of some individuals to give proper consideration to the subject.

Dr. C. R. AGNEW, of New York, remarked that an effort should be made to secure a sanitary map of the entire State, and that we should have enabling acts by which we can meet just such conditions as sanitary science may demand. One of the most conspicuous sources of evil throughout the rural districts is the improper location of wells. Many such evils may be remedied by proper measures, secured and introduced by medical men.

Dr. J. P. GRAY, of Utica, remarked that the city fathers and local authorities cannot be relied upon for any relief in the direction suggested by the subject of the evening. He regarded it as certain that relief could only come from some central power having at its head a permanent engineer, who shall have control of the entire matter. Assistants may then be located at different points throughout the State, for local authorities are generally entirely indifferent with regard to these matters. Several cases were referred to, illustrating the evil effects of improper drainage.

Dr. SNYDER, of Montgomery County, also mentioned several cases illustrating the evil effects produced by improper drainage in the development of fevers of various kinds; and if some relief could be obtained by law it would be very beneficial and desirable. He was of the opinion that cheese factories are a very prolific source of typhoid poisoning, and cited several cases illustrative of his opinion upon this point. He related one case in which he believed that a family were poisoned on account of the cows drinking water from a pond which was impregnated with drainage from a cheese-house, pig-yard, and privy.

Dr. WEY moved a vote of thanks to Gen. Vièle for his highly instructive remarks. Motion unanimously carried.

The President remarked that a committee should be appointed to take the entire subject into consideration, and that such committee should have plenary power of action. The Doctor then made quite extended remarks relative to the subject under consideration.

Dr. SHERMAN, of Oswego, remarked with regard to the location of privy vaults, and cited cases in illustration of the development of typhoid fever as the result of drinking water that had been contaminated by percolations from privy vaults.

Drs. Thomas Hun, J. P. Gray, and J. P. White were announced as a Committee upon the President's Address.

The Society then adjourned, to meet the next day at 9.30 A.M.

SECOND DAY—MORNING SESSION.

Society called to order at 9.30 A.M. Prayer was offered by Rev. Dr. Darling. Journal of previous day read and approved.

The first paper for the morning session was read by

Dr. Knapp, of New York, upon the "Pathology of Tumors of the Eyeball," illustrated by microscopical specimens.

The subject of the paper was illustrated by large mountings of tumors in glass cells, by diagrams upon the black-board, and by microscopical specimens, thereby giving both macroscopical and microscopical appearances. The specimens embraced chondromata, sarcomata, gliomata, glio-sarcomata, melano-sarcomata, etc.

Pathological changes were briefly and concisely alluded to in connection with salient points of clinical and operative importance. Some remarks were also made upon the question of diagnosis, to the effect that, in the earlier stages, intra-ocular tumors produce no irritation whatever. In arriving at diagnosis, perforation of the coats of the eye and laceration of the retina are not only justifiable, but commendable. Attention was also called to diagnosis by means of the ophthalmoscope specially devised for the purpose.

The paper was discussed by Drs. Noyes, Graves, and Rider.

Dr. NOYES called attention to the fact, in matter of diagnosis, that certain appearances within the eye following cases of cerebro-spinal meningitis, closely assimilate the appearance of intra-ocular tumors. Early diagnosis and extirpation of intra-ocular tumors is the only safe method of treatment.

Dr. GRAVES regarded it as important that we should endeavor to get behind all external manifestations, and arrive at what the change consists in which changes a normal cell into an abnormal cell; this would perhaps enable us to determine the distinction between benign and malignant forms of disease.

Dr. NOYES remarked that, practically speaking, intra-ocular tumors necessitated extirpation of the eye; so that, the fact of being malignant or non-malignant, practically, was not of such absolute importance.

Dr. KNAPP recalled a case in which operation had been performed upon an intra-ocular tumor successfully without extirpation of the eye.

Dr. RIDER also gave the history of a tumor of the iris which was operated upon, and the patient recovered with preservation of vision.

A paper upon "Hæmoptysis," by Dr. Leaming, of New York, was announced. Referred.

Report of Dr. Caro, as delegate to the Pennsylvania State Medical Society, was announced and referred. Biographical sketch of Dr. R. S. Allen by Dr. T. B. Reynolds. Referred.

Dr. JOHN P. GRAY next read a paper upon the "Pathology of Insanity." His paper was illustrated by photo-micrographs, and embraced investigations upon fifty-two cases. The results of the investigations were as follows:

In chronic mania and dementia the increase of interstitial, granular, amorphous matter and connective fibres, or, in other words, the hyperplasia of neuroglia, both in the gray and white substance, has been characteristic of the disease, reaching the highest limits ordinarily in the gray matter, and appearing more conspicuously in the anterior than the posterior region of the brain. The degeneration has usually originated in localized regions, circumscribed in a cystic cavity formed by condensed minute connective-tissue fibres.

The condition of the brain in epileptic insanity, and especially the alteration of the medulla, agree in appearance and character with those pointed out and described by Dr. Echeverria in his work on epilepsy.

An instance of syphilitic insanity, acute in character, was referred to, and the pathological change de-

scribed adds further proof of fatty degeneration which constitutional syphilis brings about in every tissue.

Special attention was called to changes which occur in acute mania. There is a uniformity of lesion in these cases. Dr. E. R. Hun has described the lesion as follows: "Examined by transmitted light they could be seen to be studded with small white spots, which were very numerous and of variable size. Under the microscope these spots presented a granular appearance, and many of them contained a number of elongated crystalline bodies of a pale greenish color. Their edges were not well defined. They were circular or oval in form, and varied in size from $\frac{1}{20}$ to less than $\frac{1}{100}$ of an inch in diameter. In some instances the nerve-fibres seemed to pass through them, but as a general rule they seemed to be destroyed." Although the cases thus far examined may be regarded as insufficient to general conclusions, they go to strengthen the conviction sustained by the laws of general pathology, that insanity is a physical disease of the brain, and that the mental phenomena are symptoms. Further, that the microscope, with patient and close investigation, will continue to disclose structural changes in the cerebral tissue, as marked as those heretofore unsuspected when examinations were limited to the scalp and naked eye; and in these investigations, when the entire range of the disease, in every stage of its progress, shall have been brought under the microscope, we may be able to solve the problem of the morbid processes denominated insanity.

Another conclusion to which these investigations would naturally lead is, that the variety and changes in the predominant symptoms of insanity may acknowledge their cause, not so much in the variety of lesions as in the special parts of the cerebral centres which are morbidly involved in each case; or, to bring the idea within narrower limits, that emotional, ideational, and motor disturbances have their foundation in the extent and degree to which the nerve elements that muster to the execution of intellectual and motor acts are involved in the lesion. When the disease reaches its ultimate stage, in all forms of insanity dementia is the final result. From continued investigations, the Doctor feels justified in expressing the same conclusions heretofore reached in May, 1873.

Dr. SQUIBB next read a paper upon "Ergot and its Preparations." In closing, he recommended oleic acid as a solvent for remedies to be applied by the *dermic* method.

The paper was discussed by Drs. Caro and Corliss.

The following were named as invited guests:

Drs. A. Van Derveer, H. S. Case, Geo. A. Jones, Albany; James S. Button, Auburn; E. G. Clark, Wash. Co.; R. J. Goodwin, Conn.; Conant Sawyer, Essex Co., N. Y.; Dr. Devoe, Albany; S. V. Morris, New York City.

Dr. SQUIBB, at this point, made some remarks regarding the liability to the production of abscess by the use of a hypodermic syringe which had been used in septic cases. Abscesses, almost indefinite in number, may be produced in this manner unless the syringe is properly cleansed. The only proper method of cleansing is to submit the needle to the flame of a spirit-lamp. This can be done without injury to the instrument.

The following report from the Committee on Publication was presented:

"The Committee on Publication would respectfully report that, for the first time in their memory, the Legislature have refused to make appropriation for the publication of our Transactions. This placed the Committee in a position in which it was delicate to act,

and the question naturally presented itself, Shall we initiate a new mode of publishing our Transactions; or shall we leave that to the action of the Society? We concluded to be guided by the Society, and carry out their directions. We would state, further, that the New York City Medical Society the Monroe Co. Medical Society and some others have lately offered to pay proportion of the expense of publication.

J. V. P. QUACKENBUSH,
H. B. WHITON,
WM. H. BAILEY.

Dr. GEORGE M. BEARD there read a paper on "A New Method of treating Malignant Tumors by Electrolyzing the Base."

Dr. BEARD stated that for three years he had been treating malignant tumors by a method which he devised and first used in 1871. He called this method *electrolyzing of the base, or working up the base*.

In the ordinary method of electrolysis of tumors, the needles are plunged directly into the growth. In the method of working up the base, the needles are not inserted into the body of the tumor, but *into and around the base*, so as to act upon the surrounding healthy tissues.

The ordinary method of electrolysis is the proper method for *navi*, benign cystitis, and aneurism, and it relieves and cures very many of these tumors, as Dr. Beard had confirmed by a variety of cases. The ordinary method is also of value in goitres and some fibrous growths; it makes such tumors smaller by a certain percentage, even when it does not cure them. Its use in such cases is now recognized.

But the ordinary method of electrolysis is not sufficient for *malignant* tumors; it but rarely cures them, even the softer forms, as epithelioma, and then must usually be several times repeated.

When the method of working up the base is used, the body of the tumor may be removed by the knife or the ligature. When the tumor is small and accessible, the negative needle is plunged directly beneath it, while the positive is applied also beneath the tumor, and very near the negative needle. With a strong current used in this way—either being of course employed—tumors of considerable size may be electrolyzed off, and at the same time the base thoroughly worked up.

Dr. Beard exhibited some long, spear-shaped needles that he had devised for the method of working up the base; also a harrow-electrode that he had devised for the same purpose.

In his experiments with this method during the past three years he had had the co-operation of very many physicians and surgeons, and especially of Dr. A. Crosby, who had worked with him in a number of cases of malignant growths of the lips, face, breast, neck, vagina, and rectum.

The advantages that Dr. Beard claimed for this method over the ordinary methods by the knife and ligature, and caustics, were these:

1. The tumors do not so readily recur, at least so far as present experience can show, provided they are so accessible that the method can be thoroughly used. Tumors which, when operated on by the knife and ligature, had recurred at once, had now stayed away one, two, and three years.

2. There is probably less liability of pyæmia. Although he had operated many times in the rectum and vagina by this method, and on debilitated cases, no case of pyæmia had yet occurred.

3. There is less liability to shock than when the knife is used. Electricity is the best of all antidotes to shock.

The two disadvantages of the method are, that it is long and somewhat tedious, and is followed in some cases by irritative fever.

The effects of electricity when used for electrolysis is mainly of a *chemical* and *local* character; destruction of tissue and cauterization are simply incidental and accompanying results, and it is by its local and complex chemical effects on the tissues around the tumor that the cures are effected. He assumed that malignant tumors were originally local diseases, and did not claim any constitutional effects from his method.

Dr. Beard stated that longer time and larger induction were needed to permanently establish the advantages claimed for the method of working up the base, and that he was still investigating the subject with the co-operation of the best surgical skill; and would report the results of his investigations at the next meeting of the Society.

ELECTROLYSIS IN STRICTURE.

DR. ROBT. NEWMAN, of New York, next presented the leading features of a paper which he had prepared upon "Electrolysis in Stricture of the Urethra." Having ascertained the number of strictures and their sensibility, and the susceptibility of the patient, the electrical apparatus is properly attached to bougies, the positive sponge is placed in the hand of the patient, the bougie is introduced to the stricture, and the battery opened gradually, using first a single cell of the battery, until slight burning sensation is produced, but not carried farther. This action produces galvanic-electric decomposition and absorption. The current must be kept steady, and all shocks avoided. The stricture can be felt to yield, and soon the bougie will pass through it. The operation should be repeated only as often as two or four weeks.

He had succeeded in all cases during three years past which had been treated by this method. Sitting at each time may be continued ten or fifteen minutes, according to the necessities of the case. Drescher's battery was regarded as being the best.

The paper was discussed by Dr. Beard, and this method of treatment was regarded as serviceable if properly and carefully applied. The kind of battery employed he did not regard as being important.

The last paper for the morning session was read by Dr. E. H. Parker, of Poughkeepsie, upon "Sleeping Doctors." The paper was a *résumé* of the methods of operation by clairvoyants and spiritualists, and some reflections upon the same, relative to the effect one mind has upon another.

Adjourned to 3 P.M.

SECOND DAY—AFTERNOON SESSION.

The first paper of the afternoon session was read by Dr. A. Jacobi, upon "Embryological Demonstrations." The Doctor first exhibited an embryo at the end of the fourth week of gestation.

Allusion was made to the development of the arterial system, and what the result would be when arrest of the development took place—for instance, at one of the common iliac arteries—all the parts which are hereafter to be supplied by this vessel will be absent. A large and well-developed specimen was exhibited illustrating this malformation.

It is probable that many cases of so-called spontaneous amputation are due to this cause. The Doctor does not regard it as probable that spontaneous amputation occurs subsequent to one month of utero-gestation. Amniotic bands may be formed so as to accomplish amputation. A specimen was also presented

illustrating meningo-encephalocele, with double sac and partial development of brain. There was a bony bridge between the two sacs, which was regarded as very unusual. This was probably due to an inflammatory hyperostosis.

Allusion was also made to the history of a case in which no hair has been developed, and the child is now four years old. The case was considered unique, and its explanation must be referred to some embryological fact. There was probably an arrest of development affecting the structures necessary for the development and sustaining of this cutaneous covering.

The next paper was read by Dr. J. Marion Sims, of New York, upon "Fibroid Tumors of the Uterus," which will appear in a future number.

Invited guests were announced as follows:—Drs. H. W. McGregor, Albany; S. W. Carmichael, Sand Lake; H. G. M. Mill, Warren Co.; J. M. Bigelow, Albany.

The next paper in order was by Dr. E. Krackowizer, upon "Perineal Lithotripsy." The paper will be published in full in a subsequent number of the Record.

The Committee upon Hygiene was then announced by the Chair, and consisted of Drs. A. N. Bell, S. O. Vanderpoel, H. D. Didama, H. W. Dean, Stephen Smith, and C. R. Agnew.

The chair remarked that, in the appointment of this committee, he did not wish to be restrictive or personal, but designed it as a recognition of the good work which had been performed by the old committee, and had made but a single change, and that was at the solicitation of the member of the old committee who had been removed.

DR. ELIOT made the motion that the committee, as now standing, be empowered to take such steps as, in their wisdom, they may deem proper for the purpose of securing such legislation upon the subject as may be necessary. Adopted.

URETHROCELE.

DR. L. B. COTES then read a paper upon "Urethrocele." The paper consisted of a history of a severe case of this affection. There is now much improvement in the patient, subsequent to the operation. Reference was made to the Transactions of 1871-2 for a complete history of the disease, and the proper point for the operation of cystotomy.

CARDIAC AFFECTIONS AND EYE DISEASES.

The next paper was read by Dr. GEO. H. STEVENS, on "The Relation between Cardiac Affections and Diseases of the Eye and Ear." Reference was made to Graves's disease, or exophthalmic goitre. This disease is known to be a nervous disease. We have reason to believe that a similar irritation of the cardiac plexus may be the cause of diseases of the ear as well as ophthalmic affections. Some cases of ear affection were referred to, in the belief that they were due to cardiac complications.

Invited guests were announced: Drs. Geo. Basten, Rondout; A. T. Douglas, Rondout.

THE SELECTION OF THE NOMINATING COMMITTEE.

Rules were suspended for introduction of resolutions. Dr. Kendall moved to take from the table a resolution which was presented last year. Carried.

The resolution, as offered last year, was then offered. The resolution is as follows:

Resolved, That the By-Laws of this Society be altered so that section 11 of paragraph 3 shall read as follows: At the annual meeting, at the close of the morning of the first day, the members of the Society shall be or-

ganized into eight Committees, by Senatorial districts, as established by the law of 1836; the members present from each district constituting one Committee, each of which shall elect one member; the members thus elected, with one appointed by the President as chairman, shall constitute the Committee on Nominations.

DR. KENDALL then discussed the resolution and urged its adoption, on the ground that the wishes of the profession in all sections of the State can be better met with regard to the formation of the Nominating Committee.

DR. POMEROY, of Wayne County, also discussed the resolution in the same general spirit, of a desire to recognize the wishes of the membership from all portions of the State. As long as the present system continues mistakes will be made and dissatisfaction be given.

DR. SQUIBB regarded the chief objectionable feature of the proposed resolution to result from the paucity of representation from the rural districts. Mistakes will be made at best; and will not the substitution of a new plan for one which now gives very good satisfaction, be somewhat hazardous so far as securing harmony is concerned?

DR. CORLISS believed it proper to cast about and endeavor to get upon the ground which would best secure the perpetuity of the Society, and now the Society is just at an important crisis, or will reach it within a short time.

The whole subject was laid upon the table indefinitely.

Adjourned, to meet in regular session Feb. 5th, at 9.30 A.M.

ASSEMBLY CHAMBER—EVENING SESSION.

Pursuant to adjournment, the Society met in the Assembly Chamber at 8 P.M., and listened with attentive interest to the valuable address delivered by the President, Dr. Moore.

After the address, the Society and invited guests repaired to the Delavan House, and were entertained by a grand collation given by Dr. John Swinburne, of Albany.

THIRD DAY—CLOSING SESSION.

Society met at 9.30 A.M., and was called to order by the Vice-President, Dr. Burdick. Prayer was offered by Rev. Dr. McGee. Minutes of previous day read and approved.

DR. S. D. BOWKER, Central City, Colorado; DR. DARWIN S. ORTON, Fulton Co.; DR. EDWARD DUFFY, Albany, were announced as invited guests.

THE PUBLICATION OF THE TRANSACTIONS.

The Committee recommend the appointment of a Committee to examine the laws and report at the next meeting of the Society what modifications, if any, are necessary touching the incorporation or organization of the State Medical and County Medical Societies; and of other matters of legislation pertaining thereto.

The Committee also recommend that State aid be no further invoked for the publication of the Transactions of this Medical Society, and that this Society publish its own Transactions; that the expense of the same be met by a system of assessments on permanent members and County Societies; that all existing permanent members be requested to pay annually to the treasurer of the State Society the sum of \$3, and that all permanent members hereafter elected be required to pay annually the same sum, which payment shall entitle them to a copy of the Transactions. That the County Societies, at a meeting before the annual meeting of the State Society, shall assess the members of the same

not less than \$1.50 each, which amount the treasurer of each County Society shall remit to the treasurer of the State Society on or before Feb. 1st of each year, which shall entitle the members of the several County Societies to one copy of the Transactions for each \$1.50 remitted. Further, that all the funds thus received by the State Society shall be appropriated to the publication of the Transactions and other necessary expenses of the Society.

Further, that the Committee on Publication shall publish as many copies of the Transactions as may be necessary, and in such manner as may be deemed most advantageous to the interests of the Society, and that not less than 1,200 extra copies be published for this year. Respectfully submitted,

THOMAS HUN,
JNO. P. GRAY,
JAS. P. WHITE.

After some discussion, the report was adopted as an experimental matter for one year.

DR. GRAY introduced the following resolutions:—

Resolved, That the Secretary be instructed to have the report of the Committee upon Hygiene and the discussion thereon printed as soon as practicable, and sent to every County Medical Society in the State as a communication from this Society.

Resolved, That the Secretary be instructed to urge upon the County Societies the importance of having Committees on Hygiene incorporated with the standing Committee on Hygiene of the State Society, and that the investigations of the County Committees in this regard, on the approval of the respective County Societies having such committees, be forwarded to the Committee on Hygiene of the State Society, in order to be summarized by that Committee in their annual report. Adopted.

ARMY STAFF RANK.

DR. SQUIBB introduced resolution relative to the rank and pay of army medical officers, heartily supporting the memorial of the American Medical Association to Congress with regard to that question. Adopted.

A paper was announced upon a case of "True Bony Ankylosis of the left Lower Jaw successfully Treated," by Dr. James L. Little, of New York. Referred.

A paper was then read by Dr. Van Derveer, of Albany, upon a "Penetrating Wound of the Cranium." The ball was removed and recovery is complete. Patient was presented.

ADJUSTABLE DRESSING FOR FRACTURE.

The next paper was read by Dr. S. F. McFarland, upon "Adjustable Dressing for Fractures." The dressing is composed of paper cut into strips from one-half to two inches in width, according to the size and shape of the part to which they are to be applied; these are to be covered with flour-paste, and adjusted to the limb in a circular and longitudinal direction, applying circular strips first. The paper should be thin, strong, and elastic. From ten to twenty layers are required. Its advantages are convenience of application; lightness and compactness; strength and elasticity; durability; readiness with which it can be adapted to the varying size of the limb by being cut open, and lacing; and the comfort of the patient. It requires several hours to get dry.

DR. MORRIS mentioned a striking illustration of American habit in eating. The man was overheard to complain of having dyspepsia. The Doctor noticed him getting outside of three boiled eggs, two good-sized potatoes, a beefsteak, a glass of milk, a cup of coffee,

a glass of water, and four buckwheat cakes at breakfast, in the astonishing length of two minutes and ten seconds of time.

Question—Was his ailment dyspepsia or barbarism? Referred.

PRIZE ESSAY.

The Committee reported that the essay upon "Colles' Fracture" had been awarded the Merritt H. Cash Prize, and that the motto of the essayist was, "The hope of an indigent devil." Upon opening the envelope there was found the name of Thos. K. Cruse, M.D., Member of the County Medical Societies of New York and Westchester.

The President announced that he had appointed Dr. Segur upon the Committee upon Hygiene, supposing him to be a member of the State Society; but as he is not, he should be obliged to withdraw the name.

The following subject was announced for the next prize:—

"School hygiene, in reference to the physiological relations of age and sex to mental and physical education."

The committee also solicited essays for the Brinsmade Prize upon any physiological, therapeutical, or pathological subject, according to election of the competitor.

The report of the Treasurer was read, accepted, and adopted.

Resolution was offered and adopted, that the Treasurer shall immediately urge delinquents to the treasury to pay up.

Dr. Wex, from the committee to whom was referred the duty of recommending to the Regents of the University of the State of New York, with regard to the appointment of a board of examiners, in accordance with the laws of 1872, presented the following names: E. M. Moore, Alonzo Clark, E. Krakowizer, John P. Gray, S. O. Vanderpoel, E. R. Squibb, John Ordronaux, A. Jacobi, and Thomas Hun.

The committee thus named were empowered to fill any vacancies which may occur.

ELECTION OF OFFICERS.

Report was adopted.

The report of the Nominating Committee being next in order, the following report was offered, accepted, and adopted, and followed by an election of the entire ticket:—

For President—Dr. Geo. J. Fisher, Sing Sing.

For Vice-President—Dr. Harvey Jewett, Canandaigua.

For Secretary—Dr. Wm. H. Bailey, Albany.

For Treasurer—Dr. Charles H. Porter, Albany.

FOR CENSORS.

Southern District—Drs. E. R. Squibb, Brooklyn; E. H. Parker, Poughkeepsie; and Elsworth Eliot, New York.

Eastern District—Drs. Henry B. Whiton, Troy; Jas. L. Babcock, Albany; and John P. Shaver, Little Falls.

Middle District—Drs. M. M. Bagg, Utica; W. D. Bassett, Cooperstown; and C. G. Bacon, Fulton.

Western District—Drs. L. B. Cotes, Batavia; Harvey Jewett, Canandaigua; and Caleb Green, Homer.

FOR COMMITTEE ON CORRESPONDENCE.

First District—Dr. Thomas Addis Emmet, New York.

Second District—Dr. Wm. P. Townsend, Goshen.

Third District—Dr. Henry B. Whiton, Troy.

Fourth District—Dr. Taber B. Reynolds, Saratoga.

Fifth District—Dr. Samuel G. Wolcott, Utica.

Sixth District—Dr. John G. Orton, Binghamton (Ch).

Seventh District—Dr. Henry B. Willbur, Syracuse.

Eighth District—Dr. Chas. E. Rider, Rochester.

FOR PERMANENT MEMBERS.

First District—Drs. Gurdon Buck, New York; and Alexander Hutelius, Brooklyn.

Second District—Drs. A. T. Douglas, Rondout; and Bradley G. McCabe, Monticello.

Third District—Drs. Alexander McVidder, Schenectady; and James S. Bailey, Albany.

Fourth District—Drs. Elisha H. Bridges, Ogdensburg; and Edmund S. Walker, Ilion.

Fifth District—Drs. Judson B. Andrews, Utica; and Wm. H. Rice, Phoenix.

Sixth District—Drs. Wm. H. Beardsley, Coventry; and E. C. Moe, Groton.

Seventh District—Drs. James D. Button, Auburn; and R. W. Pease, Syracuse.

Eighth District—Drs. Wm. B. Sprague, Pavilion; and B. L. Hovey, Rochester.

ELIGIBLE FOR PERMANENT MEMBERS.

Third District—Samuel Cross, Cobleskill; Israel C. Bourne, Masonville; and George P. Salmon, Hudson.

Fourth District—Asa W. Tupper, N. Granville; and Harvey Gray, Greenwich.

Fifth District—Jos. Gardiner; Hiram G. Dubois, Camden; and F. W. Root, East Hamilton.

Sixth District—Chas. B. Richards, Binghamton; and Judson C. Nelson, Truxton.

Seventh District—Wm. Oliver, Penn Yan.

Eighth District—Thos. D. Strong, Westfield; and J. W. Palmer, Victor.

HONORARY MEMBERS.

Drs. J. Matthews Duncan, Edinburgh, Scotland; Washington T. Atlee, Philadelphia, Pa.; William Boeck, Christiania, Norway; Benjamin W. Richardson, London, England; James W. Brown, U. S. Army; Mr. T. Spencer Wells, London, England.

ELIGIBLE FOR ELECTION TO HONORARY MEMBERSHIP.

Drs. Francisco Dicheira, Palermo, Italy; Louis Vecker, Paris, France; J. M. DaCosta, Philadelphia, Pa.

For Hon. Degree of Doctor of Medicine—Drs. Peter Denny, Dutchess Co.; William Newman, New York.

DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.

Drs. E. M. Moore, Rochester; William Govan, Stony Brook; N. C. Husted, New York; E. C. Bottini, Lyons; C. R. Agnew, New York; H. B. Whiton, Troy; A. N. Bell, Brooklyn; William C. Wey, Elmira; John G. Orton, Binghamton; Henry W. Dean, Rochester; William S. Ely, Rochester; George H. Hubbard, Lansingburg; Joseph E. West, Utica; S. O. Vanderpoel, Quarantine; H. D. Didama, Syracuse; Frederick Hyde, Cortland Village; J. S. Prout, Brooklyn; M. H. Burton, Troy; James L. Little, New York; John G. Adams, New York; Elsworth Eliot, New York; J. C. Hutchinson, Brooklyn; James P. White, Buffalo; H. L. Chubbuck, Elmira; Levi Moore, Albany; B. F. Sherman, Ogdensburg; J. Foster Jenkins, Yonkers; Francis Burdick, Johnstown; R. V. K. Moulfert, Orange; E. Krakowizer, New York; E. R. Squibb, Brooklyn; George F. Shady, New York; Thomas M. Flandreau, Utica; Israel Parsons, Marcellus.

Delegates to the Pennsylvania State Medical Society—Drs. Salvatore Caro, New York; Levi Moore, Albany; Solomon Van Etten, Port Jervis.

Delegates to the Ohio State Medical Society—Drs. Thomas D. Strong, Westfield; William B. Sprague, Pavilion; Morgan Snyder, Port Plain.

Delegates to the Rhode Island State Medical Society—Drs. J. Marion Sims, New York; Thomas Addis Emmet, New York; D. P. Bissell, Utica.

For Delegates to the Maine State Medical Society—Drs. Hiram Corliss, Greenwich; Luther Guitcan, Trenton.

For Delegates to the Massachusetts State Medical Society—Drs. John G. Adams, New York; George H. Hubbard, Lansingburg; William H. Thayer, Brooklyn; E. H. Parker, Poughkeepsie; H. K. Bellows, Norwich; Jno. P. Gray, Utica.

For Delegates to the Connecticut State Medical Society—Drs. Gurdon Buck, New York; Seth Shove, Katonah; A. T. Douglas, Rondout; James W. Minor, Brooklyn; Eugene Beach, Gloversville; Jared Linsley, New York; Bradford S. Thompson, Salisbury, Conn.

For Delegates to the New Jersey State Medical Society—Drs. Robert Newman, New York; Solomon Van Etten, Port Jervis; J. G. Orton, Binghamton; J. V. Kendall, Baldwinsville; Morgan Snyder, Port Plain.

For Delegates to the New Hampshire State Medical Society—Drs. J. H. Pooley, Yonkers; M. R. Holbrook, Poughkeepsie; Wm. M. Chamberlain, New York.

For Delegates to the Vermont State Medical Society—Drs. George H. Hubbard, Lansingburg; N. H. Ballou, Mechanicsville; J. H. Wheeler, Athens.

For Delegates to the Canadian Medical Association—Dr. Arthur S. Wolff, Plattsburg.

For Delegates to the Michigan State Medical Society—Dr. Chas. G. Bacon, Fulton.

FOR COMMITTEE UPON STATISTICS.

First District—Dr. Elsworth Eliot, New York; *Second District*—Dr. John Ordronaux, Brooklyn; *Third District*—Dr. Jos. Lewi, Albany; *Fourth District*—Dr. B. F. Sherman, Ogdensburg; *Fifth District*—Dr. Henry N. Porter, New York Mills; *Sixth District*—Dr. John G. Orton, Binghamton; *Seventh District*—Dr. H. D. Didama, Syracuse; *Eighth District*—Dr. Julius Miner, Buffalo.

FOR COMMITTEE UPON PRIZE ESSAYS.

Drs. Thomas F. Rochester, Buffalo; Henry W. Dean, Rochester; Julius F. Miner, Buffalo.

FOR COMMITTEE UPON PUBLICATION.

Drs. J. V. P. Quackenbush, Albany; Thos. Hun, Albany; Wm. H. Bailey, Albany.

FOR COMMITTEE UPON BY-LAWS.

Drs. Oliver White, New York; Thos. Hun, Albany; Wm. H. Bailey, Albany.

CENSOR OF SYRACUSE UNIVERSITY, MEDICAL DEPARTMENT.

Dr. Samuel G. Wolcott, Utica.

The following resolution, attached to the report, was also adopted:

Resolved, That as the sense of the Nominating Committee, that the President of the Society be requested to urge faithfulness on the part of the Committee on Statistics, for the purpose of eliciting the information contemplated in the constitution of said Committee.

C. R. AGNEW, *Chairman*.

WM. C. WEY, *Sec.*

Dr. Govan offered the following resolution, which was unanimously adopted:

Resolved, That the thanks of the Society are hereby tendered to Dr. Swinburne, for the banquet furnished by him last evening.

Dr. CORLISS bade the Society an affectionate farewell, not knowing but that it might be the last time he ever should meet with its members. Dr. Corliss is now 81 years of age, and is probably the oldest active member.

Dr. QUACKENBUSH offered the following:

Resolved, That the thanks of the Society be presented to the President, Dr. Moore, for the prompt, impartial, and business-like manner with which he has performed the duties of presiding officer of this Society.

Unanimously adopted.

Dr. MOORE responded, after which the Society adjourned.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 19, 1874, to February 4, 1874.

BAILY, JOS. C., Surgeon.—Granted leave of absence for two months. S. O. 15, A. G. O., January 26, 1874.

GIBSON, J. R., Assistant Surgeon.—Granted leave of absence for 40 days. S. O. 2, Division of the South, January 20, 1874.

BENTLEY, E., Assistant Surgeon.—Granted leave of absence for 30 days, with permission to apply to the Adjutant General of the army for an extension of 30 days. S. O. 11, Department of California, January 21, 1874.

TAYLOR, M. K., Assistant Surgeon.—Assigned to duty at Austin, Texas, S. O. 11, Department of Texas, January 19, 1874.

HEIZMANN, C. L., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort McPherson, Nebraska, S. O. 10, Department of the Platte, January 23, 1874.

WIRTZ, H. R., Surgeon.—Died at San Francisco, California, on January 24, 1874.

Medical Items and News.

COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.—The annual dinner of the Alumni Association of the College of Physicians and Surgeons will take place at Delmonico's, Fifth avenue and Fourteenth street, Monday evening, March 2, at 7 o'clock. Tickets, five dollars each, can be obtained of Mr. Clacher, Medical Library and Journal Association Rooms, 107 East 28th Street, New York. A general meeting of the Association for the election of officers will be held at the College, Wednesday evening, February 28.

THE SIAMESE TWINS are to be dissected at Philadelphia, under the auspices of the College of Physicians. We shall give a full account of the results in due time.

THE APPROPRIATION FOR THE ARMY MEDICAL MUSEUM, and the Library of the Surgeon General's office has been restored to its former amount. Let the profession congratulate itself that its wishes in this respect have been granted.

ON ANIMAL VACCINATION, BY FRANK P. FOSTER, M.D.—Dr. Foster wishes to make the following corrections to his remarks before the New York Academy of Medicine (vide page 22):

Page 22, vol. viii. 2d paragraph, 4th line: for "protection of vaccination," read "production of

vaccinia." 4th paragraph, 8th and 9th lines: for "Dr. Sguin, claiming to present the view taken of the subject," read "Dr. Seaton, founded on observation of the practice." 6th paragraph, 1st line: for "vaccina," read "vaccinia." 3d line: for "the protection," read "is that." 4th line: for "vaccination," read "vaccine." 7th paragraph, 1st line: omit "who introduced animal lymph." 8th paragraph, 4th line: omit "generally." 8th line: for "does," read "do." 9th paragraph, 1st line: omit "as." 2d line: for "equal," read "equally." 10th paragraph, 1st line: for "with," read "within." 2d line: omit "the animal," and, for "can be," read "has been." 3d and 4th lines: for "estimate with regard to its liability," read "elements in estimating its power."

DR. S. OAKLEY VANDERPOEL has been confirmed by the Senate as Health Officer of the Port of New York, for the next term. This is nothing more than could have been expected.

THE PHILADELPHIA OBSTETRICAL SOCIETY have elected the following corresponding members:—Drs. Fordyce Barker, T. G. Thomas, J. Marion Sims, T. A. Emmet, E. R. Peaselee, Nathan Bozeman, Isaac E. Taylor, Abraham Jacobi, of New York; J. V. P. Quackenbush, Albany; Charles Buckingham, Boston; Wm. H. Byford, Chicago; Theophilus Parvin, Indianapolis.

NEW YORK PATHOLOGICAL SOCIETY.—In our list of officers of this Society we accidentally omitted the name of Dr. J. C. Peters as editor of the Transactions.

THE MEDICAL VICTIMS OF YELLOW FEVER AT MEMPHIS.—We have received the following circular, which speaks for itself:—

"To the Medical Profession at Large: In obedience to the resolution of the Convention of Physicians, lately assembled in this city, we undertake this address to your sympathy, with full assurance that its hallowed object will secure your cordial support.

"But yesterday our community was as a house of mourning, and its wail of distress, arising from stricken hearts and desolate homes, smote the ear of the world with the horrors of our affliction. Those of our people who remained in the doomed city can alone appreciate the sad story of suffering seen and felt in our midst, when death thus held, for seven long weeks, its high carnival among us. Over the entire city death and silence brooded. Its deserted streets, alike both day and night, scarce echoed a sound save the mournful hearse-rattle as it hurried to the grave its load of dead, or the foot-falls of those ministers of mercy who lighted up the hours of darkness with their visits of charity. Silently and continually the pious labor of love was performed, and each rivalled the other in the patient discharge of a common humanity. When the shaft of death prostrated one, another, with true Corsican spirit, took his place, and the work of benevolence went fearlessly on, until, under the favor of Heaven, the disease was baffled and the reign of terror at an end. Each creed, sect, order, and brotherhood had its heroes and its martyrs, and it is in commemoration of the deeds of both the living and the dead that our hearts should never suffer forgetfulness.

"The faithful physician who survived the storm bears in his conscience its plaudits of duty done; but our seven brothers, Williams, Freeman, Crone, Hatch, Kennon, Blount, and Minor, fallen at their post, martyrs to the cause of humanity; ay, bright exemplars of professional honor and duty, sleep in their quiet graves, with more lasting glory than embalmed warriors in piles of storied marble. Our fallen brothers, if they could be consulted, would doubtless wish no fitter burial than quiet interment in leafy Elmwood; but pro-

fessional pride demands the honor of their perpetual commemoration, and we ask in this behalf that suitable stone be raised and carved for them. Their fame, the story of their heroism, belongs to the medical world, and our brethren throughout the broad land are respectfully requested to contribute something to this laudable end. Your contributions, however small, will aggregate a success of the enterprise.

"Remittances may be made to either member of the Committee—Richard H. Taylor, M.D., 44 North Court St.; F. L. Sim, M.D., 115½ Beale St.; R. W. Mitchell, M.D., 275 Main St.

"MEMPHIS, TENN., November 10, 1873."

THE METROPOLITAN THROAT HOSPITAL.—This Hospital, located at No. 17 Stuyvesant Street, near Cooper Institute, has recently been organized and incorporated with the following medical staff:—*Physicians*—Clinton Wagner, M.D., Morris J. Asch, M.D., Geo. M. Lefferts, M.D. *Pathologist*—Edward B. Bronson, M.D. *Consulting Physicians and Surgeons*—I. J. Crane, M.D., W. A. Hammond, M.D., J. Marion Sims, M.D., J. R. Wood, M.D., Max Herzog, M.D. *Medical Superintendent*—Clinton Wagner, M.D. Dispensary department open daily from 2 to 4 p.m. Laryngoscopic demonstrations given daily, to which members of the profession are cordially invited.

Medical Department of Life Insurance.

AN INQUIRY INTO THE MORTALITY OF EIGHT HUNDRED POLICY-HOLDERS, WHO WERE SUPPOSED, AT THE TIME THE POLICIES WERE ISSUED, TO HAVE A PREDISPOSITION TO CONSUMPTION, EITHER INHERITED OR ACQUIRED.*

By ALBERT H. BUCK, M.D.,

INSTRUCTOR IN OTIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

(Continued from the January 15th No. of the Record.)

THE 800 cases, upon which the following calculations are based, represent very nearly the total number of risks of this kind which the company has upon its books for the city of New York and vicinity, prior to 1872. About 700 of the number were examined by the former medical director of the company, Dr. Clements, and the balance by the physicians mentioned in the early part of this report and by myself. To facilitate the arrangement into groups or classes, all the facts of importance, either in an actuarial or a medical point of view, were written upon a separate card for each case. The groups into which the entire number were divided are the following:

1. Those who had previously had spitting of blood. 70 cases.
2. Those who had previously lost a parent from consumption. 386 cases.
3. Those who had previously lost one or more brothers or sisters from consumption. 229 cases.
4. Those who had previously lost a parent and one or more brothers or sisters from consumption. 107 cases.
5. Those who had previously lost both parents from consumption. 8 cases.

GROUP I.

Spitting of Blood.

The facts relating to this group are briefly the following: In the first place, if a proper proportion between height and weight is any indication of a good physique, the 52 cases in which these items have been recorded must have been well selected. The averages are as follows: (See Table XVII.)

In the second place, it appears that there were only two cases where the insured had spitting of blood more than once. In eight instances no record seems to have been kept of the time that had elapsed since the last

attack. In the remaining 62 cases the lengths of time were recorded, and may be classified as follows: (See Table XVIII.)

Of these cases 59 were apparently free from any hereditary taint to complicate the problem. The deaths in the entire group were 11 in number: one from dysentery, one from softening of the brain, one from intemperance, and eight from consumption (nearly 73 per cent.). There were 8 deaths among the 59 non-hereditary cases, or 1 to 7½ persons; while among the 11 cases, complicated by an hereditary taint, there were 3 deaths, or one to 3½ persons. The average age at which the 70 were insured is 36½ years; the average age of the eleven at death is 43¾ years.

GROUP II.

One Parent Consumptive.

The average age at which these 386 cases were insured is 33 years, while the average age at which the parents died of consumption is 42 years. Or, if we make two subordinate groups, one of 161 cases in which the consumptive taint came through the father, and the other of 225 cases in which it came through the mother, we shall find that in both groups the applicants averaged 33 years of age, but that in the former the fathers averaged 45 years at death, while in the latter the mothers averaged only 40 years.

Again, the relations of height to weight, in 320 individuals of the groups, are as follows: (See Table XIX.)

The deaths in this group are 22 in number: 8 from consumption, (36½ per cent.), 6 from brain troubles (27½ per cent.), one from inflammation of the bowels, one from cancer of the face, one from cancer of the bowels, one from abscess of the liver, one from dysentery, one from typhoid fever, one from fatty degeneration of the heart, and one from congestive malarial fever. Or, making the same division as before into two subordinate groups, we obtain the following results:

Hereditary by the mother, 225 policies. 15 deaths.
Hereditary by the father, 161 policies. 7 deaths.

GROUP III.

One or more Brothers or Sisters Consumptive.

This group comprises 229 cases. The average age of the applicants at the time they became insured is 36 years; the average age of 285 brothers and sisters, alleged by them to have died of consumption, is 36 years. The relations of height to weight are as follows: (See Table XX.)

The deaths in this group are 12 in number; namely,

TABLE XVII.—SPITTING OF BLOOD.

Relations of Height to Weight. 53 Cases.

Height.....	5.1	5.2	5.3	5.4	5.5	5.6	5.7	5.8	5.9	5.10	5.11	6.00

American Standard.....	125	130	135	140	143	145	148	155	160	165	170		...

4 from consumption (33½ per cent.), 3 from disease of the brain (25 per cent.), 2 from accidental causes, 1 from “dropsy,” 1 from chronic inflammation of the bladder, and 1 from cirrhosis of the liver.

GROUP IV.

A Parent and one or more Brothers or Sisters Consumptive.

The 107 applicants of this group were 35 years of age, on an average, at the time their policies were issued by the company. The average age at which the parents died is 47 years. The relative heights and weights are as follows: (See Table XXI.)

The deaths which occurred in this group are 15 in number: 10 among the 67 who received the consumptive taint through the mother, and 5 among the 40 who received it through the father. The causes of death are the following:

Six, or 40 per cent., died from consumption; three, or 20 per cent., died from brain troubles; two from typhoid fever; one from Bright’s disease of the kidneys; one from abscess of the liver; one from accidental and one from unknown causes.

GROUP V.

Both Parents Consumptive.

The eight applicants of this group were, on an average, 35 years of age at the time they became insured,

while their parents at death averaged 52 years of age. They were all of good proportionate weight. The only death that occurred in the group was due to consumption.

CONCLUSIONS.

Thus far I have simply endeavored to present, in a condensed form, as many of the facts as I was able to gather concerning the physical condition, family history, and death-record of the 800 individuals involved in the present inquiry. The great practical question, however, is: Has it paid to insure these more or less imperfect lives? If it has not, why should we continue to lose money on this class of cases? If it has, then will it be well worth our while to define the conditions or laws in accordance with which success has been obtained; and this our analysis will, to a certain extent, enable us to do.

Through the kindness of the actuary, Mr. William D. Whiting, I am enabled to furnish you with the answer to this most important question. It is embodied in the following communication:

December 23, 1873.

SIR: I have carefully examined the cards, containing the names of parties insured in this company whose family history, as taken from the applications, shows a taint of consumption, handed me by yourself. I have

eliminated therefrom all duplicate risks, when more than one policy has been issued upon the same life, thereby increasing the reliability of the results notwithstanding the smaller basis for calculation obtained.

The results, grouped as requested, are as follows, compared with the expected mortality according to the actuaries' or 17 office-experience tables.

TABLE I.

	No. of Pobs.	Exposure.	Table mort.	Actual mort.	Ratio of actual to expected mort.
One Parent, ...	386	2864½	35.52	22	61.93
One or more Bros. & Sisters, ...	229	1807½	21.82	12	55.00
One Parent & one or more Bros. & Sists.	107	768½	9.35	15	160.42
Both Parents, ...	8	63	.75	1	133.33
Insured spat blood, ..	70	495½	6.16	11	178.57
Totals, ...	800	5999	73.60	61	82.88

In order to show the relative mortality, where there is but one member of the family dying by consumption, and where there is more than one member, free from the confusion of minuter classifications, I have arranged the same risks in the following order:

TABLE II.

	No. of Pobs.	Exposure.	Table mort.	Actual mort.	Ratio of actual to expected mort.
One person in family	533	4075½	40.89	33	66.14
More than one person in family, ...	177	1428½	17.55	17	96.86
Insured spat blood, ..	70	495½	6.16	11	178.57
Totals, ...	800	5999	73.60	61	82.88

No one of these "spitting blood" is included in any other-group, as these cases were selected for the purpose of showing this important item separately without regard to family history. The enormous mortality shown, I believe for the first time, will of itself fully justify the extra labor.

I have also made a subdivision of the 1st and 3d groups for the purpose of elucidating the relative mortality when the father was the party dying of consumption as contradistinguished from the mother dying of the same disease, as suggested by you. The results, as a priori expected, are as follows:

TABLE III.

	No. of Pobs.	Exposure.	Table mort.	Actual mort.	Ratio to table.
Father died of cons'n	161	1220ys	14.86	7	47.11
Mother " " "	225	1644½	20.66	15	72.60
F. and one or more Bros. and Sisters.	40	326	3.74	5	133.69
M. and one or more Bros. and Sisters.	67	442½	5.61	10	178.24

Or, consolidating the same without regard to brothers and sisters into only two groups, we have:

TABLE IV.

	No. of Pobs.	Exposure.	Table mort.	Actual mort.	Ratio to table.
Father dying with consumption, ...	201	1546	18.60	12	64.51
Mother dying with consumption, ...	292	2086½	26.27	25	95.16

In conclusion, I would say that the most valuable results of the above, in a mathematical point of view, are those in Tables II. and IV., on account of the number of policies involved securing greater uniformity in the law of averages. For the same reason groups Nos. 4 and 5 of Table I. should be taken with much caution, especially group 4, consisting of but 8 persons, and having no value except to show that *as far as it goes* it is in the direction which would be surmised a priori. I am very much pleased to find that taking these risks as a whole, the mortality has been very favorable to the company, quite as much so as the whole number of risks at large taken by the company since its organization—which fact reflects great credit upon the discrimination of those who made the medical examinations.

Yours truly,

WM. D. WHITING.
Actuary.

From these calculations, therefore, it would seem that the excessive mortality of three of the groups (spitting of blood, both parents, and one parent together with one or more children), comprising 185 cases, is more than counterbalanced by the small mortality of the other two, which comprise in all 615 cases. It would perhaps be rash to draw the inference that cases belonging to the three groups in which the mortality has proved excessive, should not be admitted to the privileges of life insurance, but we can scarcely go amiss in rejecting hereafter all cases of "spitting of blood," no matter how long the time that may have elapsed since the occurrence of this symptom. As to the group of two consumptive parents, if we hereafter admit cases belonging to it, the applicants should be not less than 45 years of age.

In the group of one consumptive parent together with one or more consumptive brothers or sisters, the average age of the applicants is 35 years, which would imply that a fair proportion of the number were still younger; in point of fact 60 of this group were 30 years of age or younger. It would probably not be too severe a rule to accept applicants of this class only on condition that they have attained their 35th year, and that the consumptive brothers or sisters had died at a still earlier age. Otherwise the risk should be postponed until he shall have attained the age at which the brothers or sisters died of consumption. In doubtful cases some weight may be attached to the fact that the mortality is greater among those who receive the consumptive taint through the mother than among those who receive it through the father.

We cannot wonder at the low mortality in the group of one or more consumptive brothers or sisters, when we observe what care has been taken to insure only those who had passed or at least attained the ages of their deceased brothers or sisters.

As regards the group of a single consumptive parent, the results attained are so astonishingly favorable that I am afraid to recommend a course in har-

mony with the logical deductions one would naturally make. Until these results have been corroborated by future investigations, it would appear wiser to follow the rule that, where one parent has died of consumption, the applicant should be at least 30 years of age.

The mortality from consumption among these five groups bears a direct ratio to the degree of inherited taint, as will be seen in the following summary:

3d group.	One or more brothers or sisters.....	33½ per cent.
2d "	One parent.....	36½ " "
4th "	One parent and one or more brothers or sisters	40 " "
1st "	Spitting of blood.....	73 " "
5th "	Two parents.....	100 " "

As regards the physical condition of those applying for insurance, our statistics justify us only in speaking of the relations of height to weight. (It is, of course, taken for granted that we are dealing only with individuals who in all other respects appear to be healthy.) In cases, therefore, where the hereditary taint alone seems scarcely a sufficient reason for declining the risk, the fact of his being below the standard weight should render us cautious in recommending him.

THE LAW OF LONGEVITY,

WITH SPECIAL REFERENCE TO LIFE INSURANCE.

By NATHAN ALLEN, M.D., LL.D.,

LOWELL, MASS.

(Read before the American Public Health Association, Nov. 11, 1873.)*

THE subject of longevity has always attracted much attention. The art and means of prolonging life were frequently made the themes of discussion, long before the real structure and functions of the most important organs in the human body were discovered. But as the principles of physiology have of late years become better understood, new interest has sprung up in relation to all matters pertaining to health, and the inquiry is very generally raised at the present time, what are the best means of preserving life, and thus securing that great boon, longevity? Now, may there not be a great general principle or law, grounded in physiology, which may serve as a guide in these matters, and help to illustrate and explain all minor facts or secondary considerations? Is there not some standard or model established by nature herself, to which we may always appeal, and by which all doubtful questions here may be tested? From our knowledge of the laws of nature, as well as of the principles of science generally, we should naturally infer that there must be found in physiology some such general law, or such standard. Several years since, after somewhat extended observation, and no small amount of reflection and reading, I became convinced that there existed a great general law of population, or increase, as a fundamental principle in physiology, and that this same law of propagation (subject to certain conditions) extended throughout the whole animal and vegetable kingdoms. If such a law in nature does exist, it might be inferred that it would have some connection with the greatest amount of health and longevity.

LAW OF PROPAGATION.—This law may be briefly defined thus: it is based upon a perfect standard of organization, or consists in the perfectionism of structure; or, in other words, that every organ in the human body should be perfect in structure, and that each should perform its legitimate functions in harmony with others. Taking this, then, as a standard, we have a

great law or principle pervading all organic matter, that furnishes a guide by which all deviations from this model, and the manifold changes that follow, may be explained and understood. While this law is subject to certain conditions, as food, climate, exercise, etc., all these act as secondary agents or factors. They may modify the operation of the law, but cannot change its nature or general character.

Evidences in proof of such a law may be deduced from physiology itself, from pathology, from the laws of hereditary descent, from the effects of intermarriage of relations, from facts gathered in the history of different families, and changes in numbers, as applied to distinct classes, races, and nations. But without dwelling upon these points, we maintain that the organization upon which this law of propagation is based, presents also the only true standard in physiology for the greatest amount of longevity—of health—of physical strength and happiness, as well as of beauty in form and outline.

LAW OF LONGEVITY.—But it is proposed to consider here only the application of this law to longevity. By this term is meant long life—the greatest duration of human life, whether in isolated cases or in large numbers. Where, then, are these cases found—what is their character—and what are the facts attending them?

In the first place, it is very evident that long life is not dependent alone upon food, nor upon climate, nor upon exercise; neither is it found in any one locality, nor with any one people, nor in any particular station; neither where great riches nor excessive poverty abound. It is sometimes found in the city, but more generally in the country.

All must admit that some of these conditions are very important, and that good health and long life must depend greatly upon the manner in which the relations between the various parts of the system and these external agents are carried on. But after all, may there not exist a general law in the body itself upon which these depend? If we had perfect standards of organization around us upon which this law is based, its truth would be more easily demonstrated; but instead of such, we have only approximations, and these in almost endless variety and form. In order that we may have a clearer and more definite understanding of the foundation of this law, let us carefully examine its physiological conditions. Every animal organization is complex—is composed of many distinct organs. Each organ has a specific work to do, and in its normal state must do so much and no more. Now in the healthiest and most perfectly organized structure, all these separate organs are found not only in a perfectly healthy condition—each one performing its own normal functions—but well balanced and working harmoniously together. In this state "the wear and tear," or the demands which nature makes to support life and carry on its operations, come upon all these organs alike, each according to its own nature, without infringing upon that of any other.

THE HUMAN BODY COMPARED TO A MACHINE.—In the promotion of health and longevity, too much stress cannot be attached to the importance of preserving this harmony or balance of organization. In some respects, the human body may be compared to a perfect machine, made up of many complicated parts. How different the working or running of such a machine from that of one imperfectly constructed and unequally balanced in all its parts! The one seldom needs repairs, the other frequently. The one will last, as it were, for an age; the other becomes almost useless in a short time.

* Reprinted from the *Sanitarian* for February, 1874.

It is so in reference to the human system. Whenever a certain organ or class of organs becomes relatively too large or too small, causing a want of balance or harmony in their action, there must be, in the very nature of the case, far greater liability to disease. Accordingly, it is in persons possessing this imperfect, ill-balanced organization, that we find not only the greatest amount of sickness, but that which is most obstinate and fatal. How often it happens that some slight derangement or trifling weakness operates as the entering wedge to the most serious diseases! It is the weak spot caused by inheritance, or developed by exposure, where disease finds its germ or starting-point, though all other parts of the system are in a perfectly sound condition; and not unfrequently life is terminated by a single organ, or even some part of it giving out, when all the other organs might have performed their healthy functions for many years.

We dwell upon the importance of this harmony or balance of action in the vital forces, for it is the great secret of good health and long life. It is a cardinal point in the law of longevity, as will appear from a more full sketch of its foundation.

PERFECT STRUCTURE AND HARMONY OF FUNCTION.—It is upon this perfect structure or anatomy of the body, combined with the normal action of all its physiological functions, upon which we base this law of longevity. It is true we have no such perfect standards or models of human organization now existing, but only approximations towards them. Still the law may apply to such as we have, just as well as the general law of gravitation or attraction to the smallest-sized bodies. We can readily conceive of such standards, and how the same law that governs them may be applicable to their representatives of whatever grade or character.

All the pains, the weaknesses, and the diseases of the human body, are but the result of deviations from this normal state; and all the means and agencies employed for the preservation of health and life look towards restoring this standard. It is well known that there are influences constantly operating to produce changes both in the structure and functions of the system. Some of these agencies have their origin internally; some act entirely external to the body, and others operate by what are called laws of heredity. By some of these influences the physical system is improved and perfected, but by others the deviations from a healthy standard are increased more and more. Probably the most powerful of these forces is that of inheritance. This agency constitutes a very important element in the law of longevity. All writers upon this subject place this condition as first and foremost—that one of the almost indispensable requisites for long life is good healthy stock, or long-lived ancestry. For it has been found by universal observation and experience, that the representatives of such stock live the longest, and that very seldom, if ever, are found persons of great age originating from feeble and short-lived ancestry.

LAW OF INHERITANCE.—Now what is the secret of this transmitted power that conduces so much to longevity? May there not be some general principle or law involved in these changes from hereditary influences, which may aid us in explaining the why and the wherefore? We know well the effects of such power, but what is the explanation—what is the philosophy involved? Under the law in nature that "like begets like," and that when the producing forces are sound and healthy, it is found that their offspring will partake of the same character, and that under favorable circumstances this may be continued for several genera-

tions. Sometimes there is an improvement in the stock; but not unfrequently a deterioration, especially after three or four generations.

Now what is the peculiarity or type of organization here perpetuated? What are its elements or constituents? What makes it long-lived? Do we not find that it consists in a sound, healthy structure of every part of the body, and that there is a remarkable balance in all the organs and harmony of functions? We venture the assertion that such will be found the character of this organization in every instance, and that there are no exceptions to the rule. Does not this, then, afford evidence that there is a general law in nature conducive to longevity, and that this law is based upon that organization which is most perfect, and all of whose functions act most harmoniously? Let us apply the rule to such individuals and families reaching a great age, that have come under our own observation. For many years I have verified the fact in numerous cases, and have never found an exception.

There is another point of view whereby this law may be tested. Certain physiological conditions have been laid down by some writers as sure indications of longevity. These conditions embrace the healthy performance of the functions of all the leading organs of the body, and may be summed up under these heads: Respiration, Digestion, Circulation, Assimilation, and Secretion. Where all the vital forces connected with each of these departments of physiology are found to operate regularly and vigorously, they are thought to be the sure indications and precursors of longevity. Now what does this imply but soundness of structure and harmony of function? Let any one of these fail in the least of performing its part, and all suffer. Does not this view of longevity, then, furnish strong evidence in favor of the law which has been set forth in this paper?

SIGNS OF LONGEVITY.—There is another class of facts which has an important bearing upon this question. These are what are denominated the physical signs of longevity. There must be a symmetrical development of the whole body. The head must not be too large or too small. The neck must not be too long or too slender. The chest must be well developed, but the abdomen must not be too large. The whole body must be well proportioned, not too tall nor too short. No class of organs must be too predominant; or, in other words, the Temperaments must be properly mixed or blended, especially the Nervous and the Sanguine, possessing more of the vital organs, must not be very conspicuous. There are some minor signs, such as the voice, the teeth, the color of the eyes and the skin, the quality of organization, etc.; but when we sum up all the foregoing signs, do they not clearly point to a harmony or balance of all the organs of the body, and thus confirm the truth of the law of longevity as here advocated?

There is a large body of facts also connected with the cure and prevention of disease, that has a direct bearing upon this subject. All sound medical treatment and means for the promotion of health operate in harmony with this great law of longevity. They aim to restore the normal structure and healthy functions of every part of the body.

In all works treating of longevity great stress is laid upon the influence of climate, food, air, water, exercise, etc. Statistics show that, while the extremes of either heat or cold are not conducive to long life, a moderate climate in countries where the changes of temperature are neither too great nor too sudden, is decidedly favorable. But even here there must be a strict observance of hygienic laws. In relation to the

right kinds of food and drink, pure air, healthy localities, dwellings, employments, etc., however important, they are all secondary agencies, and operate under and in harmony with one great general law.

MENTAL HYGIENE.—But there is still another class of facts differing from any of those mentioned, that has a powerful influence upon longevity, viz., the influence of mind upon the body. Mental training, a well-balanced mind, a cheerful, contented disposition, and temperate habits, are, with rare exceptions, found indispensable. Now these presuppose a harmonious development of the whole body, and particularly of all parts of the brain. For it is impossible, we believe, to obtain the qualities here mentioned in a high degree without these two conditions. And the nearer this development approaches that standard of organization upon which is based the great law of longevity, the greater will be not only the aggregate amount of health, but the longer the duration of human life. This statement will be found abundantly verified in the history and character of persons who have reached a great age.

This interdependence of body and mind is becoming every year better and better understood. It is found that the relations of the mind to the body, and of the various states and changes of physical organization to the mind, have a powerful influence upon health. And the more marked and abnormal the differences in this relation, the more striking are the effects. If, then, health is so dependent upon the state and relation of these two agents, the duration of human life must be most sensibly affected by it. And we venture the assertion, that the more thoroughly this particular feature of the subject is investigated, the more important and far-reaching will be found the influence of these reciprocal relations. The evidences derived from this source will go far, we believe, towards proving that nature has established a certain harmony or equilibrium of action between the body and the mind, and the more perfect that development and harmonious the performance of their respective functions, the nearer is the approach to that standard of organization upon which is based the law of longevity.

This view explains, in part, why the average age of man has been increased by education, and that the greatest longevity is found among nations most highly civilized. In confirmation of this remark, a distinguished writer says: "That type of civilization in which the efficiency of the community and of the individual is greatest, in which there is the most harmonious action between the body and the mind, the greatest happiness of the greatest number, the least excessive expenditure with the least luxury, where regularity and temperateness are innate characteristics, will be that state of civilization most favorable to longevity." It is scarcely necessary to say that such a type of civilization could not exist without well-developed physical organizations generally, and a harmonious action of all the mental faculties.

Another well-known writer on this subject, after enumerating among the prerequisites to longevity, temperate and regular habits, a cheerful and contented disposition, says there must be not only an equilibrium of the mental faculties, but a descent from long-lived ancestors, a tranquil and happy temperament, and general symmetry of physical conformation, and harmonious proportions of all the different parts and organs of the body.

Numerous quotations might be cited from other authors, and many additional facts might be gathered from various sources in support of this theory of

longevity; but our present limits will not permit. Perhaps the theory of one writer should not be passed by unnoticed, inasmuch as it may be thought to have some resemblance to the one here presented.

THEORY OF M. FLOURENS.—M. Flourens, in a very elaborate treatise, maintained that man ought by virtue of his natural constitution to live a hundred years, and that this natural term of life is abridged only by his own improvidence, follies, and excesses. The length of human life he attempts to establish by the law of growth and by analogy, viz., that every animal will live, on an average, five times the period of his growth. Thus, as it is found by anatomy that it takes, on an average, twenty years for man to reach his perfect growth, especially the bony structure, the limit of life would be one hundred years. Flourens held that neither climate, nor food, nor race, nor any external condition had much to do with the duration of life, but this depended almost wholly upon the natural constitution, and the intrinsic vigor of all the organs of the body. But he does not define very clearly how this natural constitution is based upon the anatomy and physiology of the system, nor attempt to show what are its laws and relations to the external world. We all know that climate, food, and other external agents have a powerful influence upon the development and preservation of the body. One great defect in his theory is, that he does not point out distinctly the great laws of health and life as based on physiology and external nature, which extend not only through individual existence, but are universal throughout creation. As to the question, what is the natural period of human life, provided all the conditions are favorable, perhaps he is not so much out of the way, though the testimony of most writers would place the limit somewhat less. Flourens presents us no standard of organization as a perfect model of imitation, and upon which the great laws of health and life must be based. If we take into consideration the structure and functions of the human body—the design of its existence, and its adaptation to external objects—there must be certain relations and fixed laws that govern in all these matters. For illustration, there is a fixed law that exists in the relation of pure air to the healthy functions of the lungs. It is so in reference to all other parts of the body. Now it is in the summing up of all these laws as applied to a perfect organization that we find the law of longevity. All the great laws of nature that are fixed and universal are invariably found based upon her works in a normal state, or in their most perfect development. As in painting and statuary the artist has constantly in his mind an ideal model, a typical standard which no living beings have ever reached but only made approximations to, so in physiology it is easy to conceive of a standard which represents an organization in its highest state of development. It was with reference to the making up and arranging the constituent elements which enter into such a standard that led the most profound physiologist in our country, Prof. Draper, to make this remarkable statement: "The approach to precision in these hypothetical constants will in all times be a measure of the exactness of physiology, and, it may be added, also of the practice of medicine. The time is at hand when such a typical standard must be the starting-point for pathology; and no rational practice can exist without it. The passage of physiology from a speculative to a positive science, is the signal for a revolution in the practice of medicine."

ADVANTAGES OF THE LAW OF LONGEVITY.—The question may very properly be asked, Supposing there is such a law of longevity, what are its advantages? We answer, many and great. It is not a mere specu-

lative theory or vague hypothesis that cannot be comprehended or applied to any practical purpose. It harmonizes not only with all the well-known truths of physiology and pathology, but is sustained by all the agencies employed by nature or art for the protection and preservation of life. In fact, it is that great general law established by the Creator himself for perfecting and prolonging the life of every human being, of which all minor laws are a part and parcel. It holds up before us that perfect form and image in which man was created, and presents an embodiment of those laws and conditions with which we must comply in order to secure the greatest amount of happiness and the longest duration of life. With such a standard constantly before us, shall we not make greater efforts to conform to it than if we had no such conception? Besides, by means of understanding the various deviations from this perfect standard, we obtain a better knowledge of the infirmities, the liabilities, and the weaknesses of the human system. It presents a new stand-point from which to survey the causes of disease, as well as the agencies employed for its cure and prevention. It gives us a clearer and better understanding of the principles of hygiene and sanitary law, and enjoins the absolute necessity of observing them, if good health and long life are to be secured. It shows that all the changes which occur in the human system are subject to law; that disease, of whatever type and character, or wherever found, is a violation of law; and all treatment and remedies, whether provided by nature or art, must be viewed as agents or means to repair the injury.

APPLIED TO LIFE INSURANCE.—But there is one use to which this law may be applied of incalculable value. We refer to Life Insurance. This is becoming an immense business, scarcely surpassed in interest and magnitude by that of any other in the country. From the best sources of information, it is estimated that there are over five hundred thousand, or half a million of lives insured in over two hundred different companies, and the amounts invested and at risk would startle one not accustomed to figures. The largest proportion of this business has sprung up within twenty or thirty years; and what is singular, the larger the business and the wider its expansion, the greater the changes in its management, and the more uncertain are its results. We should naturally suppose that time and experience would give permanence and stability; but what a sad spectacle is presented by the rise and fall of so many Life-Insurance Companies as have occurred—some of them, too, after many years apparently of successful experience! What a history of wrecks, losses, and disappointments does it exhibit! Scarcely can a parallel be found in the history of any other incorporated business in the country.

Commencing more than thirty years ago as an examiner for Life Insurance, appointed by the London Loan Office, and having since been connected as an examiner with several other companies, I have become more and more convinced that there was here room for great reform. But there are some questions on this subject of great interest, which we cannot discuss, but which, under other circumstances, might claim attention; our present object is simply to show wherein this law of longevity may be applied with great success to Life Insurance.

In the examination of any organic structure with reference to forming an estimate of its continuance, we must understand correctly its nature and construction, as well as the laws that govern its action. If it is made up of many parts or distinct organs, we must comprehend fully their relations to each other and to external

objects. But in order to make the best use of such knowledge, and form an intelligent estimate of results, we want some general law or standard of appeal, which shall be applicable to the whole. To any one acquainted with the earlier history of the different sciences, it is well known what great advantage was found when a large body of facts or amount of knowledge had been obtained, that by the discovery of a general principle all these facts and this knowledge could be more systematically arranged and satisfactorily explained. It is somewhat so in applying this law of longevity to Life Insurance, though it may be subject to many conditions, and cannot be reduced to mathematical accuracy.

PREREQUISITES OF LONGEVITY.—Without explaining again this law and its conditions, let us briefly notice some of its applications in determining the prospect or continuance of life. All the essential elements or prerequisites for longevity may be conveniently arranged or summed up under three distinct heads, viz., *constitution, inheritance, and obedience to law.*

1st. It furnishes the examiner for Life Insurance with a standard of organization, with which the constitution of all persons examined may be compared, and which will assist in forming a correct judgment of their soundness, or in detecting the physical deviations from a normal standard; then what are the liabilities to disease, and what the prospects or probabilities of life. Without such a standard or guide we have no general rule to test the soundness or strength of the constitution. It must depend very much upon opinion merely, which, of course, will vary according to the differences of judgment in different individuals. With such a model constantly before us as nature has furnished, we can understand more exactly and fully the relations which all parts or organs of the body sustain, one to another, as well as to external nature; and then we can calculate or forecast far better the changes to which they may be subjected. The more of such knowledge we possess, the more accurately can we estimate the continuance or prospect of life.

2d. **LONG-LIVED ANCESTRY.**—All writers upon Life Insurance lay great stress upon inheritance, or a long-lived ancestry. This has been found by universal experience to be one of the prerequisites, in fact an indispensable condition, of long life. Now, why—why is this so important? What are the reasons—what does it mean? What is the rationale of it, or what lessons does it teach? Does it not clearly and distinctly imply, that if there is any truth in this power of inherited organization for long life—the more perfect the organization the greater the power—there must certainly be found, somewhere in nature, a great general law of longevity? The influences of hereditary descent have as yet received but little attention, compared with their importance, even by the medical profession, and before they can ever be thoroughly understood, it will be found, if we mistake not, that there exists in physiology, as a fundamental principle, a general law of propagation, and as a part and parcel of the same, will also be found this law of longevity. In the matter of Life Insurance, a thorough knowledge of these hereditary influences is of the utmost importance.

3d. **CONDITIONS OF HEALTH.**—Obedience to law. This has a very wide application, including all the physical laws, and relations of body and mind. The better these laws and relations are understood, and the more strictly all are observed, the greater will be the amount of health, and the longer human life. But in order to effect this most successfully, the conditions of good health must first be fully understood, such as

pure air and water, wholesome diet and drink, healthy vocation and residence, regular hours of exercise and sleep, temperate habits, right mental and moral culture, with a cheerful, contented disposition.

With the increased knowledge and observance of these laws of health, many individuals have not only prolonged their own lives, but the average duration of human life, within forty or fifty years, has considerably advanced. But physiology in its practical applications is yet in its infancy. When its principles become so generally understood and appreciated as to be practically applied throughout the community, in every family, and by every individual, then will be found a great diminution of disease, as well as of early mortality. Now, by having a true standard of organization for testing a good constitution, and by understanding correctly the laws of hereditary descent, it gives us new and more definite views of the various conditions of health. In the examination of persons for Life Insurance, all these laws or conditions must be taken into account, and after careful and thorough investigation, it will finally be found that all these principles and agencies operate in harmony with, and are based upon, one great general law in nature—the law of longevity.

The question may still be asked, Wherein, how, or in what way more in detail, can this law be made practical? To answer this question fully would require a volume. Only two or three further suggestions can here be offered.

It points out directly the true means or sources of health and life,—that there is no chance or mystery in them, but that they are all governed by laws which can be understood and obeyed. It expounds correctly the great laws of inheritance which furnish the groundwork—the prerequisites for good health and long life. It explains the absolute necessity in the outset of a sound constitution, of a well-balanced organization. It shows the relation and importance which human agency holds in propagating a sound and healthy stock. It teaches every individual more clearly what are the peculiarities and weaknesses of his own constitution, as well as what are his particular dangers or liabilities to disease. It is this exact, this definite and personal knowledge that may be turned to the greatest account in the prevention of disease. If every individual in the community could be thus made acquainted with his own physiology, together with the laws of hygiene, we should soon see a most surprising difference in the relative amount of sickness as well as of early mortality. And who can appreciate the advantages of such a law, or make so good an application of it, as the well-educated physician, whether he be in private practice or holds some official position before the public?

Miscellaneous.

ANSWER TO COMMUNICATION.—To R. S. C., of Illinois, we would reply, that the quickest way to correct the evils of which he complains is for every respectable physician to refuse to act as examiner for any Life-Insurance Company that knowingly allows "Eclectics, Botanics, Homoeopaths, Cold-water Doctors, Snapping Doctors," etc. to make medical examinations for them. Something like united action on the part of the reputable physicians in the State would soon bring these loosely-managed companies to their senses, and compel them to employ exclusively either the "Cold-water Doctors" or the regulars.

A GOVERNMENT CHOLERA COMMISSION.—The Hon. J. Proctor Knott, formerly a Representative in Congress from Kentucky, has written letters to Congressmen and to the Surgeon-General, urging a Government investigation of the origin and spread of the cholera last summer. The Surgeon-General indorses Mr. Knott's suggestion, and to-day the House passed a resolution, on motion of Mr. Dawes, directing the investigation to be made by one or more army surgeons detailed for the purpose. Medical officers, with special qualifications for the work, will be assigned to this duty, and it is believed that the result of their inquiries will throw much new light upon the subject, and be of great interest to the medical and scientific world. All the localities where the disease raged will be visited, and the experience and opinions of local physicians and Boards of Health will be considered.—*New York Tribune*, Jan. 8.

"REMARKABLE ACTION ON A LIFE-POLICY.—A very singular case of action upon a life-policy was this week submitted to the Civil Tribunal of Paris. The circumstances are so curious that we give the facts in extenso, as we find them related in the report of *Galignani*. It appears that in Sweden, as in England, it is not unusual for people to effect, by way of speculation, insurances on the lives of individuals not connected with them. In 1855, one Svenson, of Carlsrona, insured the life of an old soldier, named Hoffstedt, of the same place, in the Mentor Company of London, for 8000 rixdollars, and in the Paternelle Company of Paris, for 7,500 francs. In August, 1856, Hoffstedt died, and Svenson claimed the amount insured in the two offices. The Mentor Company paid at once; but the Paternelle Company thought fit to institute an investigation respecting the death. It then turned out that Hoffstedt was a confirmed drunkard, and that Svenson supplied him money to enable him to drink brandy in excess, his object being, it was affirmed, to hasten his death. The old soldier at last died very suddenly, and the rumor was spread that Svenson had poisoned him by putting arsenic in the brandy. The dead body was examined, and arsenic was found in it. Svenson was consequently arrested and brought to trial before the Criminal Court of the district, on the charge of poisoning. But the charge could not be established. He was acquitted. As, however, he was proved to have had arsenic in his possession—and in Sweden this is illegal for a private person—he was fined sixteen rixdollars. On an appeal, the judgment was confirmed. The public prosecutor then petitioned the King to cause the man to be imprisoned in a fortress, on the ground that there was no moral doubt of his guilt. In August, 1857, his Majesty refused this petition; and at length the man was released. Meantime he had become bankrupt. The assignees now instituted proceedings for payment against the Paternelle Company, in Paris. The ground on which they based the action was, that the judgments of the Swedish courts proved clearly that no murder had been perpetrated, and that the company could not prove that Hoffstedt committed suicide, so the insurance remained valid. The company, however, contended, first, that the judgments of the Swedish courts were not binding in France, and consequently that their acquittal of the man amounted to nothing in the eye of the law; next, that as Hoffstedt had undoubtedly died of poison, it was clear either that he had committed suicide, or that he had been poisoned by the man who was to benefit by his death, either of which cases, in France, rendered an insurance invalid. The Civil Tribunal, adopting the arguments of the company, rejected the action."—*Lancet*, Dec. 10, 1859.

LARYNGEAL PHTHISIS.

READ BEFORE THE MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

By R. P. LINCOLN, M.D.,

NEW YORK.

(Concluded from page 86.)

SYMPTOMATOLOGY.

WHATEVER be the cause of laryngeal phthisis, we always have a chronic inflammation to deal with, subject to exacerbations due to intercurrent acute attacks. There is, therefore, no well-marked difference in the subjective symptoms of this affection over other chronic laryngeal diseases.

In addition to the sensation of tickling, which this affection shares in common with all other inflammatory diseases of the larynx, usually the first symptom of which the patient complains, and which leads him to consult his physician, is a cough. This, which at first may be but a slight and ineffectual effort to clear the throat, gradually attains a more pronounced character, and often becomes spasmodic in its nature. The sound of the cough, being modified by the same organs that form the voice, corresponds in a degree with it. When we have dysphonia, we will have a rough, hoarse cough, entirely destitute of resonance; this may be due, not necessarily to a deficiency of volume of air from the lungs, but to the action of the glottis (the healthy explosion of which, so to speak, gives the clear ringing cough), that is impaired either by some obstacle that prevents the contraction of the muscles, or by some modification of the cords themselves.

The patient will sometimes give you an account of an attack of sore throat, from which he thinks he never entirely recovered, but as often he cannot lay claim to any exciting cause so definite. With the increase of the disease the cough will become excessively harassing, particularly at night, and almost always aggravated by a change of temperature, as when going from a warm room into the outer air, or *vice versa*.

The vast majority of patients complain of pain of a dull, aching character, and often of a smarting and burning, amongst the early phenomena. At first this is not increased by pressure, but later in the disease, when the tissues are much swollen, it is much aggravated by pressing the larynx back or by compressing its ale.*

Distinct from the sensation of pain, but closely allied to it, is that of dryness, which is alone very distressing, and not allayed by frequent applications of fluid.

You will also be told of difficulty in deglutition, and of actual pain in the effort, as well as in the act, of swallowing. This occurs when the epiglottis is thickened or destroyed in whole or in part, so that its office is imperfectly performed, and particles of food or liquid, which is more liable to happen, passes within the larynx and excites spasmodic coughing.

When there is much œdema within the larynx, and particularly when the arytenoids and their appurtenances are involved—and they almost never escape—their compression by the muscles of deglutition may be attended by so much pain that the patient will often abstain altogether from attempting to swallow, and, unless efforts for relief are availing, we may literally

witness the unpleasant spectacle of a starving and famishing patient.

Disturbance of respiration does not attract attention under ordinary circumstances till the disease is some what advanced. Almost the first of the phenomena of this derangement occurs only during inspiration, the sound becoming rough and sufficiently audible after exercise to attract attention, while the expiration may be without effort and natural. Should an acute laryngitis occur during this stage we will have a stridulous respiration, and the recovery from the attack will be more than usually slow; but ordinarily the dyspnoea is in proportion to the development of the disease.

If there is co-existing pulmonary disease, particularly if there is much debility, a panting respiration, after even slight exertion, will be an early symptom, which the patient will wait to recover from before replying to your questions.

When the calibre of the glottis is encroached upon, either by sclerosis or by œdema, we will have constantly all the symptoms of œdema glottidis, and at all times the respiration will be labored, while in the last stages of the disease there will be paroxysms of dyspnoea, suffocative in their nature, which the patient often calls asthmatic. These paroxysms, which commonly at first make their attacks at night, a little later are excited by any violent exercise, and are attended with a sense of oppression, and often with a flushed or livid condition of the face, and an anxious expression to the whole countenance, even when there is no disease in the lungs themselves, though that will make this symptom much more marked.

The function of the larynx is of course always impaired in this affection. In the early stages of the disease the voice may only have its quality slightly altered, but before the second is passed there will be complete aphonia, which at first may be remittent, but sooner or later constant; at first there may be only a weakness after use, to be restored by rest; but in a short time it becomes continually husky with an indistinctness, then a uniform hoarseness and discordance, and finally only a rough whisper.

Simple weak phonation usually attends, and is consequent upon a general congestion of the mucous membrane of the larynx, with its consequent dryness, and perhaps slight tumefaction; huskiness upon the thickening of the vocal cords.

The complete loss of voice depends upon ulceration of different organs, particularly of one or both vocal cords, and upon œdema.

This inequality or discordance of the voice is often noticed in laryngeal phthisis, and cases have been reported by Merkel and Türk where a double tone was produced, and explained by a collection of mucus between the vocal cords and ventricular bands, and by growths and polyps on the vocal cords dividing the glottis into unequal parts.*

The expectoration in simple laryngeal phthisis is almost always of a moderate quantity, and varies in character with the different stages of the disease, from a frothy mucus, in the first stage, to purulent, with, at times, traces of blood, and exceptionally the debris of disintegrated cartilage.

Before the disease has very far advanced, the product of the muciparous glands becomes, in consequence of the congestion, quite gelatinous, when the sputa will resemble prepared starch; this often contains dark particles from the inspired air, or what Dr. S. Scott Alison has described as the carboniferous corpuscle. Some times the frothy mucus will contain small but distinct

* Late in the disease, to which there are very few exceptions, when the pain becomes excessive in the larynx, it extends with equal severity to the ears and down the neck to the shoulders.

* Quoted in Boston Med. and Surg. Jour., Nov. 21, 1872, p. 358.

drops of pus, and even blood, which are thrown off, circumscribed ulcers or sinuses leading to the seat of a former abscess; at other times the sputa will be uniformly purulent, but varying in degree and very tenacious.

Usually the sputa is raised with some difficulty, and after repeated efforts by a process of clearing the throat rather than by a deep cough. This is caused in the first stages of the disease more by the congested and swollen state of the parts than by the amount of the sputa; but later the tenacious muco-purulent sputa may be comparatively abundant and yet adhere strongly to the bottom of a large but superficial ulcer. If there is accompanying pulmonary phthisis or chronic bronchitis, the abundance of sputa from this source will mask any distinguishing features of the sputa of laryngeal phthisis.

An appearance of blood in the expectoration is not unfrequent during the course of the disease. It is usually small in amount, continues but for a brief time, and occurs at short intervals.

Coming on usually after an effort of coughing or clearing the throat, the sputa is then streaked with bright arterial blood, though sometimes a small clot will be thrown off, in which case it may be of a darker color; in the first instance it is seldom so intimately mixed with the clear or yellow sputa as when it comes from lower down in the air-passage and when in clots, usually smaller than when it comes from the lungs.

The discharged blood may issue from any of the tissues of the larynx. When the mucous membrane is highly congested, as may be the case whatever be the stage of the disease, some small blood-vessel may be ruptured in the violence of coughing and a small quantity of blood escape. We have seen it *in situ*, having burrowed under the mucous membrane a short distance, as sometimes occurs beneath the conjunctiva, from injury. The same condition is also sometimes seen in the pharynx. Hemorrhage may also occur from a blood-vessel divided in its course by the progress of an ulcer.

Emaciation is not a prominent symptom in simple uncomplicated laryngeal phthisis, except in the very last stages, when it is a result, less of a consequent drain on the system than on account of imperfect deglutition, labored respiration, and wearing cough that interfere with the repair of the system, arterialization of the blood, and restorative sleep.

Under the same circumstances as the loss of flesh, when a hectic condition supervenes, we will have a harsh, dry state of the skin, with rarely a slight elevation of temperature; this latter is insignificant when compared with the analogous state in pulmonary phthisis.

It rarely happens that the digestive organs evince any morbid action in this affection, certainly not directly in consequence of it.

The partial loss of the hair, weakness of the sexual instinct, absence of the catamenia, and other evidences of wasting of the bodily powers, so commonly early observed in patients subjects of phthisical degeneration in other organs, are not observed in simple laryngeal, except it has lasted a long time and has proved nearly destructive to life.

Before the invention of the laryngoscope the only means of mediate investigation was the "tactus-eruditus," which could have been of little service, except to detect destructive action of the epiglottis, and in another condition which often forms one stage of this affection, viz., edema glottidis. Dr. Buck has given full and careful directions how to conduct this means of exploration. It depends upon a thorough knowl-

edge of the anatomy of the parts and a familiarity of touch.*

By means of the stethoscope we can detect, when there is much mucous or pus present in the larynx, large, moist, and sub-crepitant râles. When fluid is not present, we will get a high-pitched sound in respiration, as an evidence of constriction. These sounds will, of course, be most strongly marked at the point of greatest interference with respiration, and through the tissues of the neck transmit the sound with remarkable distinctness, yet it will generally disappear as our examination is extended towards the lungs.

Ocular inspection of the pharynx in this affection, when there is associated tubercular cachexia, discloses a marked anemic appearance, and at the same time unusual capacity (probably from atrophy). This condition should always invite examination of the whole respiratory tract.

It needs no argument from us to convince you of the superior advantages of the laryngoscope over all other means of investigation. It reveals to us, with no chance for error of judgment, all the pathological changes we have previously described, except, of course, those deep in the substance of the tissues, and these even are attended with superficial changes from which we can infer the former.

We have reflected in the laryngeal mirror, first, the epiglottis, which we may find anemic, congested, swollen, or red, distorted or destroyed in different degrees. We may find the mucous membrane of the whole larynx in an unusually pale, almost transparent state, with here and there red velvety patches, or, perhaps, small points of ulceration. At other times there may be seen a general condition of congestion of the whole laryngeal mucous membrane, even including the vocal cords.

The appearance of the interior of the larynx, so far described, is characteristic of all forms of chronic laryngitis. However, as the disease progresses and infiltration occurs, we find a degree of swelling takes place at certain parts that is highly characteristic. The outline of the arytenoid cartilages becomes transformed into pyriform-shaped bodies, with their base situated posteriorly and apex upward, forward, and outward; the ary-epiglottic folds participate in the formation of this tumor, which may at first involve only one side, but sooner or later extends to the other. When both sides are thus affected, the two will be seen in contact in the median line; or they may even become so large as to intercept a view of the parts below. These tumors are of a pale color, and usually covered with mucus and pus given off their ulcerated surfaces. When suppuration takes place within them, its evacuation is attended with a diminution in size, and pus can be seen escaping from the opening, which often enlarges so as to expose the diseased cartilage at its bottom.

The ventricular bands often appear distended, overhanging the vocal cords themselves, while the latter are often seen highly inflamed, losing their characteristic white color, or ulcerated at the processus vocalis and along their margins, the borders of which are sometimes studded with small granulations of a polypoid appearance.

DIAGNOSIS.

There are but few morbid conditions of the larynx whose lesions are liable to be confounded with those of this affection. Its beginning is, as we have seen, often insidious but progressive, though at times it may supervene on an acute laryngitis, in which case there is nothing characteristic in the local primary manifestations; its objective symptoms are manifested in the

* Trans. A. N. Med. Ass., vol. i., 1848, and vol. iv., 1851.

voice, cough, respiration, etc., and are, therefore, common to nearly all organic alterations depending upon inflammation, ulceration, and edema. We are, therefore, compelled to make our chief dependence for reliable diagnosis upon the evidence furnished by the laryngoscope. The obstinate progress of the disease, its long standing, the harassing cough and general constitutional deterioration, with the considerable thickening of the parts, are among the differentiating points to be considered in distinguishing this affection from chronic laryngitis. In this latter disease we always have an active bright red-congestion, which involves also the pharynx, and this, with the uvula, are generally relaxed. Another distinguishing mark is the superficial nature of this ulceration compared with that of laryngeal phthisis. The microscope is of service here.

In simple catarrhal laryngitis the mucous secretion is effected without a destruction of the epithelium; * while in the first lesion of laryngeal phthisis this is destroyed, leaving a new mucous surface, which pours out a muco-purulent secretion.†

Formerly it was necessary to describe in detail the symptoms to distinguish spasmodic asthma, but now we can determine at a glance the presence or absence of organic changes, though the complete remission of the dyspnea in the one case, and its stridulous character in the other, is usually sufficient to distinguish the affection.

Acute edema is recognized by the sudden onset of the attack, previous freedom from symptoms of disease, and the transparency of the tumor, which is the only local evidence of disease.

The majority of the benign growths that appear in the larynx are readily recognized by the aid of the laryngoscope, many of them being pedunculated or sessile, and not intimately blended with the adjacent tissues.

Cancerous growths are not so easily distinguished from appearances exhibited in certain stages of laryngeal phthisis, and our diagnosis will rest, in addition to the information supplied by the constitutional history and objective symptoms, on the fact of its being blended thoroughly with the surrounding tissues, extending beyond the larynx, and not involving both sides to the same extent. Displacement of the larynx by the growth is common. When the malignant growth becomes ulcerated, the discharge has a characteristic offensive odor. A microscopic examination of fragments will often aid us in these cases.

Syphilitic lesions frequently locate themselves in the larynx, and often give evidence of their presence in a similar manner to like lesions of laryngeal phthisis. The collateral symptoms that exist, or may have existed, on the skin and elsewhere, are of prime importance as an aid to differential diagnosis. Syphilitic ulcerations in the larynx are very commonly extensions of similar conditions in the nasal fosse, palate, or pharynx, while in laryngeal phthisis this is rarely the case. In the latter disease the mucous membrane is usually paler than normal, even when there is considerable thickening; in syphilitic inflammation, on the contrary, it has a dusky color, which by some is considered pathognomonic. There is nothing characteristic in the form or locality of the ulceration. Trousseau quotes Dr. Krishaber as authority for the statement that simple non-diabetic ulceration of the larynx is the most destructive.‡ But it certainly is not rare to find the

epiglottis completely destroyed by syphilis. There is, however, comparatively less thickening of the tissues, though the superficial ulceration may be larger in syphilis than in phthisical laryngitis. The same authority states that the aphonia of syphilis is almost always caused by a puffy state of the superior vocal cords, and that of laryngeal phthisis is more commonly caused by ulceration and inflammation of the vocal cords proper.

Warty growths, or condylomata, are often seen as a result of syphilis, but never in laryngeal phthisis; they are observed as whitish, uneven elevations on the mucous membrane, which sometimes ulcerate and always quickly disappear under proper treatment. They are not likely to be mistaken for the small, polyp-like bodies on the edges of the ulcers sometimes seen in laryngeal phthisis. In syphilitic laryngitis the epiglottis is most frequently the first seat of attack, and the mucous membrane covering the arytenoid cartilages the last, even after the vocal cords and other parts of the larynx; while in laryngeal phthisis the ary-epiglottic folds, particularly at the point of the arytenoid cartilages, are first in the order of attack, the epiglottis later, and after it the ventricular bands and vocal cords.

The principal lesions not present in syphilis, but which are almost constant in laryngeal phthisis, and peculiar to it, are the pyriform swellings of the ary-epiglottic folds and ulcerations, preceded by a thickening of the tissues and of a slow and chronic disposition.

PROGNOSIS.

Were the disease purely local, our prognosis would be favorable; but when we consider it a local manifestation, modified by a cachectic constitution, our prognosis must be unfavorable, except our patient early present himself, and before any other important organ is seriously impaired. There may be cases, well advanced too, of recovery, as there are instances of recovery from pulmonary phthisis, but they are comparatively few in number. As is often the manner in pulmonary phthisis, so in laryngeal phthisis, death may result not so much from the local trouble as from the combined depressing and wasting influences of intercurrent maladies. Doubtless cases are reported by competent authority where death has resulted from the hectic fever, harassing cough, emaciation, and debility, when no other disease has supervened; but usually the immediate cause of death in such patients is asphyxia. Many escape a fatal termination—how many we cannot tell—so uncertain is the diagnosis in the very beginning of the affection, and this fact should be a sufficient monition for an early and general examination whenever the laryngeal affection shows a tendency to persist. Local treatment modifies very much the course of the disease; the edema may be reduced, the congestion relieved, and the ulceration often healed. A few cases may recover, but we can almost always afford our patient at least temporary relief from suffering and prolong life.

TREATMENT.

Treatment can naturally be considered in its three aspects—preventive, remedial, and palliative.

The first consists of a correction of any morbid habit or tendency of the system, and controlling, without delay, any slight manifestation of disease in the throat. There is no affection where the importance that general treatment should be early entered upon is more manifest. Correct the tendency to degeneration, and half the battle is won; but if this point has been passed,

* Rindfleisch, in Archiv. f. Path. Anat., von Virchow, t. xxi.

† Dict. Encyc. des Sci. Méd., p. 644.

‡ Clinical Lectures, Amer. Trans., vol. iii., p. 106.

and irregularities are already established, it is of even more importance to correct them.

In the list of causes, we have considered at sufficient length the different conditions that seem to invite laryngeal phthisis, and it is unnecessary to repeat general rules of treatment for the different cachexia so often associated with this disorder.

It is a good axiom never to allow, if we can prevent it, the system to harbor anything evil.

If, for instance, a patient presents himself evidently debilitated, and illy nourished and generally deteriorated, in consequence of a strumous diathesis, and there is reason to apprehend any laryngeal trouble, there is at once suggested a residence for the summer at the sea-side, or for the winter in a more equable climate than ours; pure air and proper exercise in it, nourishing but unstimulating food, warm clothing and avoidance of excess of all kinds, whether in the use of the voice or in overtaxing body or mind. If sea-bathing is not practical, salt-water bathing, cold in hot weather and warm in cold, to insure a free action of the cutaneous surface. The strength of the patient must be early considered, and remedies directed that will tend to increase constructive metamorphosis, give vigor to the solids, and vitality to the blood. The destructive metamorphosis should be checked till at least it is more than counterbalanced by the reparative power.

Catarrhs of all kinds, wherever situated, should receive due attention, as well as excessive menstruation, when it exists.

For remedies, food, tonics, cod-liver oil, iron, sulphur, and arsenic, may be severally indicated when the digestive functions are well performed. When the building-up process is once established, iodide of potassium will often increase it. Should reflex irritation from the lungs or any distant part be threatening, some of the bromides may be of service, and if there is already a congestion or inflammation in the air-passages below the larynx, some inhalation of an astringent, sedative, or antiseptic nature will be of much service; carbolic acid thus employed has often seemed to us to allay irritation there, and thus indirectly prevent trouble in the larynx.

If pulmonary phthisis exists, though it even be an advanced stage of the preceding diathesis, what we have said there will equally apply here, and, if possible, should be insisted upon with even more emphasis, because of the gravity of the complication.

We will only refer here to the value of counter-irritation over the diseased lung, and caution against the use of iron and stimulants during the inflammatory states.

Inhalations, if properly administered, are always of advantage, whether antiseptic, as carbolic acid, or soothing and sedative, as preparations of tar, bromide of ammonium, steam, etc.: these will always have a favorable influence on the cough. Should the statement of Niemeyer, that the sufferer from pulmonary phthisis has most to fear tuberculosis, prove to be correct, we have a powerful weapon in antiseptic inhalations. The syphilitic drouths, and any special diathesis, the presence of whose poison in the system is impairing it, must be each combated.

The remedial measures will be chiefly directed to the local manifestation of the disease, and at the same time those should be employed calculated to prove effective against any intercurrent disorders resulting therefrom. The cases where the affection is purely local, or where it is but slightly modified by some cachexia, afford the most encouragement for the success of treatment whether general or local. The latter has the most power to back the tide of disease, and the former to preserve the ground gained, and prevent a relapse.

When we have the first lesions, congestion and erosion to deal with, a spray of some astringent, as solutions of tannin and glycerine, of alum, of the sulphate of zinc, or of iodine, will be of the utmost value; at the same time some counter-irritant over the larynx and on its sides, by means of tincture of iodine, thepsia plaster, or croton oil; when this is not sufficient, a small blister at the point indicated, especially on the access of an acute exacerbation, to be allowed to heal at once, and again repeated rather than to be managed as an issue; if the latter object is sought, we would prefer to place it at a distance, as on the nape of the neck.

When the mucous membrane and submucous tissue is hypertrophied, no remedy, locally applied, will accomplish so much as solutions of nitrate of silver of different degrees of strength, and applied in the form of a fine spray.

Of all remedies for topical application, none is so much used, and none so much abused, none has stronger advocates or more bitter opponents, and probably none so generally useful, though, when misused, capable of doing greater harm, than nitrate of silver.

If there is much oedema, it must be relieved by scarification, advantageously followed by some one of the previous remedies, or by the application, in which case it is to be very circumscribed, of the chloride of zinc or of gold, by means of saturated lint on the end of a probe.

When there is much acute congestion or inflammatory swelling, and the mucous membrane livid and dry, inhalation of steam or of some balsamic fluid, or the local spraying with tannin and glycerine, will sometimes unload the vessels and give relief without incision. Should an abscess make its appearance, its early evacuation by free incision will limit the destruction, relieve the pain, and perhaps prevent suffocation.

When ulceration is present, extending into or deeper than the mucous membrane, or acting on a cartilage, as the epiglottis, nitrate of silver will be of great service, or chromic acid with one-fourth its weight of water. Iodoform, in the form of a powder, we have found particularly useful in aiding cicatrization and stopping pain.*

Of associated or intercurrent disorders pharyngitis is very common, and may demand active attention. Most of the affections of the pharynx are similar to what we have described as occurring in the larynx, and the course of treatment pointed out for the diseases of the latter is adapted to them also. In addition thereto, when we have a congested or hypertrophied state of its mucous membrane, with dryness or diminished secretion, chlorate of potash, preferably in the form of troches, is of great value: while in the opposite condition, when the parts are relaxed and flabby with excess of secretion, lozenges of tannic acid or kino are serviceable; but if they are merely irritable and sensitive, bismuth, gum-drops, marsh-mallow or slippery-elm decoctions will be grateful. The patient can co-operate effectively, when the pharynx is involved, by employing solutions of alum, tannin, and salt, in the manner of a douche, directed against its walls; † the remedies thus used being far more profitable than when managed as a gargle.

If enlarged tonsils be a source of irritation, their speedy removal will be called for.

Sometimes a febrile state, greater than would be expected from the lesion alone, will be met with, in

* For cases illustrating its use by the author, see THE RECORD for Sept. 15th, 1873, p. 449.

† For a description of this method by the author, see THE RECORD for Nov. 1st, 1873, p. 551.

which case it will be advantageous to administer alkalies, as the carbonates of soda or potash; or if a state of atony or anemia, iron, quinine, or strychnia, or, which is a good combination, their phosphates, according to the formula of Aitken.

Should a diarrhoea make its appearance, it should always receive immediate attention. Remedies called for as curative will, of course, when it is too late in the disease to expect recovery, have a palliative influence.

It should be our pleasure as well as duty to tax our energies to assuage suffering, for under the most favorable circumstances, when the disease goes to a fatal termination, or when it attends death from any other cause, much distress will rarely be avoided. Our resources are many, and our means of reaching the disease most complete.

One of the chief sources of danger in the last stage of laryngeal phthisis is death from apnoea, on account of closure of the glottis from oedema. Though the risk to the patient is less now than formerly, on account of our improved facilities of treatment, yet its possibility should not be overlooked, and we should be prepared to perform tracheotomy as a last resort when necessary.

Porter strongly advised it, though it was first suggested by Bryant.

Porter went so far as to practise it early in the disease as a method of treatment: his object was to put the larynx in a state of rest, the most favorable for recovery. If there is necrosed cartilage that is causing irritation and that threatens suffocation, tracheotomy may give a chance for its safe removal and healing of the wound.

There is much encouragement for this proceeding, if no other part of the system is so far diseased as to be itself a source of danger.

The pain and sense of constriction, which often extends from the larynx to the shoulders and to the ears, are best relieved by stimulating or hot external lotions; these are best applied on spongio-piline, which can be fitted to the neck, and we can thus avoid the weighty poultice.

When this pain in the ears requires interference, anodyne applications in the external auditory canal will sometimes notably give relief, and it is the testimony of a patient now under our care, that relief also extends to the larynx.

The best local anæsthetic in our hands has been iodoform, applied directly to the ulcerations after the removal of the discharge. This is best done by means of a curved tube, provided with a piston, which, under the direction of the laryngeal mirror, can be easily used.

We shall always have occasion, in this stage of the disease, to employ those soothing and mechanical remedies previously spoken of, and we might advantageously add thereto preparations of refined chocolate, which nourishes as well as soothes.

REPORT OF CASE OF REMOVAL OF A FOREIGN BODY FROM BLADDER BY PERINEAL SECTION.

A NOVEL METHOD OF EXTRACTION.

By GEO. C. SMITH, M.D.,

RONDOUT, N. Y.

JAMES K., resident of this village, aged 24, good health, cooper, while experimenting (as he says) with a glass tube, attempting to pass the same as a catheter, which he thought it resembled, had the misfortune to

break the tube within the urethra, the distal portion slipping at once into the bladder.

In great alarm the patient withdrew the other portion, and threw it out of the window, into the snow below, and it was lost; but the patient thought at least three inches in length remained within.

The case came into my hands on the following day, February 13th, 1871, and an operation for its removal was at once set down for the 14th (day following), and patient was prepared for perineal section by lateral operation. Operation was successful and recovery quick, and complete restoration of all his functions. The flow of urine per urethra was re-established on the 19th, and on the 7th of March patient was discharged cured.

The tube proved to be three inches long, size of No. 9 catheter, slightly curved from end to end, and as frail as an ordinary silver catheter would be if made of glass, smooth at one end, but rough in fracture at the other end; and in manipulating with forceps, after it had been seized, it became necessary to inject the bladder with warm water, in order to disengage its ends from the folds of the cyst.

The chief point of interest to the profession in recording this case, is the successful application of an ingenious device by my friend Dr. A. T. Douglas, of this village, who was associated with me throughout the operation and subsequent treatment. The tube was known to be long and very fragile, and it became desirable to remove it without breaking, if not already broken; and at the suggestion of the Doctor the jaws of the forceps were coated with "taffy" (molasses-candy), to secure adhesion and protect the glass from fracture, and also being soluble at the temperature of the body, not liable to leave any nucleus behind for future calculus.

CASE OF RETENTION OF URINE FROM ENLARGEMENT OF THE PROSTATE.

USE OF THE ASPIRATOR FIFTEEN TIMES—REMARKS.

By S. FLEET SPEIR, M.D.,

SURGEON TO THE BROOKLYN CITY HOSPITAL, SURGEON TO THE BROOKLYN EYE AND EAR INFIRMARY, ETC.

Mr. R., aged 64 years, healthy, with a previous history of slight trouble of the urinary organs. On Monday, December 1st, 1873, I was called, in consultation, by Dr. W. K. Brown, to see this patient. He had been suffering from retention of urine since early Sunday morning, and since then occasionally a drop at a time would come away. I found the bladder greatly distended, reaching nearly to the umbilicus, and the patient had suffered most intense pain during the previous night from distention. This pain had been relieved by Dr. Brown by means of morphia suppositories and laudanum injections in large doses. When I saw him, Monday noon, he was free from pain, and under the influence of the anodynes; he had had a comparatively quiet night. I endeavored to pass the usual urethral instruments, and failing with them, tried Squire's vertebrated catheter, using two sizes, but without success. As I had previously used this instrument successfully in similar cases, I concluded that there was more than ordinary obstruction. I then tried the various modifications of the elastic catheter, but with similar result. I succeeded, however, in passing a filiform bougie into the bladder, and followed it by a grooved canula of small size, but there was no flow of urine; and after patient efforts at catheter-

ism I concluded to use the "aspirator," as the case was growing more and more serious, and relief from the distended bladder was demanded immediately. I therefore introduced the trocar of the aspirator above the pubes, and drew off (2) two pints (3) three ounces of urine, with perfect relief to the patient. He passed a comfortable night, and in the morning began to feel some sense of fullness of the bladder, and at 1½ A.M. I relieved him of 2 pints of urine by the same process, Dr. Brown having in the meantime tried to introduce the catheter. I also tried to introduce the catheter before and after "aspiration."

On careful examination per rectum, the prostate gland was found considerably enlarged, and there was tenderness on pressure. The prostate seemed to rise above and obstruct the opening of the urethra in the bladder. This attack of retention was the first ever experienced by the patient, although he had at times some trouble, on rising in the morning, to get the urine to flow, but he has always succeeded in emptying the bladder in a few minutes without much trouble. He had recently been exposed to cold, and his attack was attributed to that cause.

I tapped the bladder eleven times during the week following, sometimes once in twenty-four hours, and sometimes twice in twenty-four hours, and in the meantime made efforts at catheterism, hoping to get through the urethra as soon as the irritation and swelling had subsided. The result of each effort being negative, I finally passed a filiform bougie and urethrotome of Maissonneuve, and performed his operation of "catheterism à la suite." After this operation I was able to pass at once a large-sized silver catheter into the bladder, but to my surprise no urine flowed. I was sure that the catheter was in the bladder, from its position, etc., and could only account for the urine not passing out through the catheter, by the probable want of tone in the walls of the bladder. I applied pressure to the abdomen, but no flow of urine following this, I attached the end of the catheter to a rubber tube, and then to the point of the aspirator, and exhausting the syringe looked expectantly for the urine to flow (supposing that a clot had obstructed the eye of the catheter). Even now no urine came, and I was obliged to trust to a reintroduction of the catheter on the following day for better results (being sure that the catheter had entered the bladder and the road was clear, but for some obstacle which I could not understand—perhaps too small quantity of urine, etc., etc.), the bladder having been aspirated previously. This was left to Dr. Brown. That night he introduced the catheter, but no urine flowing, he was obliged to "aspirate" the bladder again; and he, supposing that possibly the catheter had not entered the bladder fairly, and that there might still be some obstruction, did not send for me until he had found it necessary to use the aspirator four times more. He then sent for me to see the case again. I found no difficulty in introducing the catheter into the bladder (same as immediately after the urethrotomy), but again no urine flowed. I was now very confident that all was ready for the emptying of the bladder through the catheter, and that by a more thorough use of the aspirator attached to the catheter we must succeed. I therefore adjusted the rubber tube with care, and we exhausted the air as completely as possible, the patient experiencing no pain. I was sure we were in the bladder, otherwise the mucous membrane would have been drawn into the eye of the catheter, and given pain, so we continued the pressure and watched the end of the tube. Presently a thick, ropy, tenacious mucus appeared at the end of the tube; so dense and tough was it that it

could scarcely pass, and hung from the end of the tube until it reached the bottom of the vessel. By exhausting the syringe more carefully, and by pressure upon the abdomen, we succeeded in drawing off about one-half pint or more of thick, tenacious mucus. The aspirator was removed, and some tepid water was injected with great ease into the bladder, and a portion of it was drawn off again by the aspirator attached to the catheter.

The next day aspiration through the catheter was resorted to again, and after injecting the bladder with tepid water, and making pressure over the abdomen, we succeeded in returning the injected water, mixed with mucus, *through the catheter, without the aspirator*. It came very slowly at first, and only by means of strong pressure over the abdomen. After this the bladder was emptied regularly, through the catheter, by Dr. Brown, and occasionally injections were made. The patient was taught to use the catheter for himself, and he is now doing well, the mucus having almost entirely disappeared.

I have reported this case to illustrate the great value of the "aspirator" in the treatment of difficult cases of retention of urine, as well as to mention a few points which seem of interest in the case.

The bladder was tapped over the pubes, in all, fifteen times, without the slightest discomfort or injury to the abdominal walls. The introduction of the point of the trocar, after the method of using the hypodermic syringe, without incision of the skin, gave a smaller wound and was more satisfactory than the incision. An important point to be attended to when frequent punctures are needed, is to see that the point of the instrument is withdrawn only when there is a perfect vacuum; then all urine and blood that might possibly lodge in the punctures will be sucked out, and the wound firmly closed and clean.

Although there was no genuine stricture in this case, the management of it was greatly assisted by the operation of internal urethrotomy.

I desire especially to draw attention to the great accumulation of mucus that may take place in the bladder after repeated tapping with the "aspirator." The upper portion of the urine is usually drawn off (the patient lying upon the back), and there is a constant accumulation or deposit of mucus and salts at the bottom of the bladder; and in cases of vesical irritation or inflammation it may become *very dense and tenacious*, obstructing the eye of the catheter and giving rise to the suspicion, on the part of the surgeon, that his catheter has not reached the bladder, or that there is but little urine present, when, in fact, the reverse is true, and all that is needed is a sufficient force to compel the thick mucus to pass.

This case is also instructive in showing the necessity for injections into the bladder in all cases where repeated tapping is likely to be needed. This should be done through the tube of the aspirator, and the fluid withdrawn again by the same means. In this way the collection of mucus would be prevented.

ON THE REMOVAL OF GROWTHS BY THE ELASTIC LIGATURE.—In a letter to *The Lancet* of Jan. 3, Sir Henry Thompson further explains the application of this method, and says that having found that the india-rubber tube which he employed in the case reported did not quite answer the purpose, he has had made an india-rubber cord, which, before application, is in size about as follows: . When applied it should be strained until it is a mere thread—say like this: 

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

HYPODERMICS OF TR. DIGITALIS.

A WOMAN was brought into the medical wards who was suffering from cardiac disease and its attendant phenomena. The lesion was mitral regurgitation. Her feet and limbs were very edematous, her heart was acting in a very irregular manner, and there was almost constant vomiting. The patient had been accustomed to taking digitalis for the purpose of obtaining relief from palpitation, which had followed her for many years. She had rheumatism fourteen years ago. Her vomiting prevented the administration of any remedy by the mouth, and drachm doses of tr. digitalis were administered by injections into the bowels. Failing to obtain the effect desired, quieting of irregular action of heart and production of diuresis, by administering the remedy in this manner, resort was had to hypodermic injections of gtt. vj. doses of the tr. digitalis, with the happy result of relieving the palpitation and increasing the amount of urine several ounces within the first twenty-four hours. Acupuncture was also employed, and a large quantity of fluid drained from the limbs in that manner. A few days after admission the patient was quite comfortable, could lie down, and had the appearance as though she might pass along for some time.

Some of the leading changes, pathologically speaking, which are developed in connection with this class of cases, are, first, acute articular rheumatism; engrafted upon this, an endocarditis affecting the mitral valves and parts adjacent, giving rise to new growth of connective tissue, which produces thickening and shortening of the valves, consequently permitting regurgitation upon the auricle and pulmonary veins and capillaries. Immediately following comes the hypertrophy and dilatation of the right ventricle, which, in part, overcomes the pulmonary obstruction. When the dilatation has occurred, there probably have changes taken place in the air-vesicles, consisting of a dilated and tortuous disposition of the capillaries upon the walls of the air-cells, and an accumulation of large cells within the air-cells. The large epithelial cells contain granules of pigment. To this change the term brown induration, or pigment induration of the lung, has been ascribed. The obstruction produced by filling the alveoli more or less with these cell-bodies is the gravest part of the lesion, as it immediately affects the respiration and forms an important element in estimating prognosis. There are also changes in the walls of air-cells.

This group of changes may occur in connection with any disease which prevents free passage of blood from the left auricle to the left ventricle. Subsequent to the hypertrophy and dilatation of the right ventricle comes regurgitation from right ventricle into right auricle, and, consequent upon this an obstruction to the general return circulation becomes established, and from this stagnation are developed pathological changes affecting the liver, intestinal tract, and kidneys. The obstruction being felt in the capillaries, gives rise to dropsies. This patient has been suffering from an accumulation of fluid in the cellular tissue of the lower extremities. When such dropsy manifests itself in the pulmonary tissue, giving rise to oedema of the lungs, the complication is exceedingly dangerous, and prognosis exceedingly grave.

MITRAL OBSTRUCTIVE MURMUR WITHOUT MITRAL STENOSIS.

Such a murmur was developed in a case of general cardiac dropsy, was unusually diffused and quite loud.

As commonly occurs in this class of cases, an opportunity for post-mortem was presented, and when the heart was examined not a particle of stenosis existed at the mitral valve. There were aortic lesions present, and it is thought that the presence of aortic lesions is a necessity for the development of such a murmur without lesion at the mitral orifice. There was aneurism of one of the aortic valves. The explanation is, that the regurgitant current into the ventricle is sufficient to close the mitral valves, and when the auricular contraction comes, the murmur before the first sound of the heart is produced. By some eminent observers the existence of such a murmur, without the lesion of mitral stenosis, is denied. There was no hypertrophy in this case.

THERMOMETER ON HAND.

In absence of a thermometer, almost every man has one ready for use, and that is the *back of the hand*. It is far more delicate than the palm or surface, and will recognize changes very accurately, although it is not ordinarily self-registering, except when the right hand is employed.

TROUBLESOME SYMPTOM.

A man, who was thirty-three years of age, had a cardiac murmur, heard just after the second sound, and with greatest intensity at the base. It was believed that the murmur was at the aortic opening, and that the second sound heard was produced by the closure of the valves upon the right side of the heart. Had rheumatism eleven years ago; and has suffered no special inconvenience until within three years; his *troublesome* symptom has been *palpitation*. Attacks of palpitation would come on, and continue for two or three weeks, and then he would get better, and so on. The treatment of such a case, of course, is hygienic rather than therapeutic. Something, perhaps, may be done for the relief of the palpitation in such cases. It is said that when the hypertrophy exceeds the dilatation, or there is no degeneration of the cardiac walls, the use of prudent doses of aconite or veratrum will often cut short an attack of cardiac palpitation. Sometimes when the action of the heart is very irregular, and the impulse feeble, the organ apparently emptying itself but imperfectly, ext. nux vomica administered in from $\frac{1}{4}$ to $\frac{1}{2}$ grain doses, three times a day, will set things right and establish quietude at once. It is in this condition that digitalis is serviceable.

ROOSEVELT HOSPITAL.

CHRONIC BRIGHT'S DISEASE.

A CASE of this kind was noticed which presented some features of interest. The patient was a woman, and fairly nourished. At the time of her admission she was passing only a small quantity of urine, which contained albumen, hyaline, and granular casts. She was immediately placed upon a free milk-diet, without any medicinal treatment whatever. Her general condition at once began to improve, and urine was passed in increased quantities. At the present time the quantity of urine is nearly normal, and at the last examination contained less albumen, and only granular casts.

Since her admission she has suffered from a dis-

agreeable and depressing complication, namely, ulcerative stomatitis. The factor of the breath was almost intolerable, the ulcers upon the tongue and cheeks were numerous, and some of them were quite large. The opinion was expressed by one of the visiting physicians that the condition of the mouth was dependent solely upon the condition of the teeth. The teeth were very badly decayed. For the relief of both mouth and teeth, a solution of hyposulphite of soda was employed, and the ulcers were dressed with iodoform. Recovery from the stomatitis was quite rapid and agreeable.

ANGINA PECTORIS.

This is one of those neuralgic affections which fills the patient with fearful apprehensions, in addition to the actual suffering experienced. Its history has so far been perfected that it can hardly be said to indicate the existence of any particular cardiac disease, and, indeed, it is believed that the same train of symptoms may occur, independent of any form of cardiac disease. The latter, however, is regarded as being rare. In the present case there was no physical evidence of chronic valvular disease. A murmur was heard at the base of the heart, but it was thought to be anemic. The patient was a woman. She was receiving quinine and iron regularly, and the attacks of angina were subdued with Hoffman's anodyne in drachm doses, p. r. n.

INSOMNIA IN PHTHISIS.

In connection with this disease the above symptom is of very frequent occurrence, and not unfrequently demands a wide-awake physician to improvise means for its relief. Morphine is chiefly relied upon in this hospital. In certain cases—those in which great irritation of the throat is present—insufflation of morphia serves a most admirable purpose, both for relieving the irritation and subduing the cough. Consequent upon this, rest is also very often secured.

Various instruments have been devised for the purpose; but a simple instrument is made by attaching a quill to a piece of rubber tubing. The quill may be loaded with the quantity of morphia desirable to administer, carried to the back portion of the mouth, or into the pharynx, and then unloaded by blowing through the tubing attached.

TYPHOID FEVER.

In this case the eruption had been very well marked. The patient occupied a bed in the common ward, and no fears were entertained that the disease would be communicated to the patients occupying the same ward, or even adjoining beds. The patient was being supported by easily digested and fluid food, such as milk, etc. No special medicinal plan of treatment had been instituted.

ASTHMA.

The patient who was suffering from this affection had, as is ordinarily the case with this class of cases, tried an almost indefinite number of remedies in the hopes of obtaining relief; but no remedy had been found which gave such complete relief as morphia used hypodermically.

The condition of the man was sad indeed. When admitted he had been in the habit of receiving a hypodermic injection six times a day, containing from 10 to 15 drops of Magendie's solution, and almost every puncture had produced a troublesome abscess. He is now receiving eight drops four times a day.

His entire body is so completely covered with ab-

scesses that a fair share of his time is occupied in fixing favorable locations for future punctures. One day this patient had suffered but very little from his asthma; but suffered equally as intensely from mental depression, believing himself to be one of the vilest of sinners, etc.

When his asthmatic symptoms returned, his mental anguish disappeared. It was remarked by one of the visiting physicians that this was a nervous development not very uncommonly met with in connection with asthma.

SYPHILIS AND PHTHISIS.

The question has been raised as to whether there is any connection between these two diseases in the relation of cause and effect. Some observers have arrived at the conclusion that such a relation does exist. Our attention was directed to the case as being one in which there was, at least, an apparent relation of cause and effect between the two affections.

The patient was first admitted to the surgical division because he was suffering from syphilis. For the syphilis he was there treated. When admitted, and previous to his admission, he was, to all appearances, a healthy man, with the exception of the syphilis; but since his admission to the hospital he has become the subject of phthisis, and has been transferred to the medical division. The question is, Is syphilis a cause of phthisis? Is it more liable to follow syphilis than many other diseases? Is it the syphilis, or the treatment usually instituted for its removal, that predisposes to phthisis? Has the question of hereditary or acquired taint, or a union of the two, anything to do with a satisfactory solution of the question?

REMOVAL OF FIVE INCHES OF SCIATIC NERVE.

This patient was a female, and had been admitted to the hospital on account of a tumor which was situated in the posterior portion of the left thigh, which was then giving her considerable inconvenience, although it had been first noticed more than a year.

It was decided to remove the tumor. When cut down upon, it was found to be intimately connected with the sciatic nerve, and to such an extent as to preclude all possibility of its removal without completely removing a large portion of the nerve. A halt was made, and a counsel held with regard to the proper method of procedure. It was decided to remove as much of the nerve as might be necessary to permit the removal of the tumor, and await the result. Accordingly, about five inches of the nerve were removed, the wound dressed, the patient placed in bed, and the result of the operation anxiously awaited. The patient was discharged from the hospital within three weeks, with but slight impairment of motion and sensation.

Progress of Medical Science.

PRURITUS HIEMALIS.—In the *Philadelphia Medical Times* of January 10th, Dr. Duhring describes a form of pruritus which does not appear to have been previously recognized. The affection is termed *pruritus hiemalis*, the attributive denoting its distinctive peculiarity. It is essentially a pruritus of cold or wintry weather, making its first appearance usually with the first decided change in weather between autumn and winter, and continuing for a variable length of time usually till the winter season is somewhat advanced, when it spontaneously subsides, often to recur the following year.

The affection is unaccompanied by any primary lesion apparent to the eye. Subsequently, however, the usual lesions due to scratching are commonly present. The disease is often confined to the lower extremities, its most favorite seats being the ankles, calves of the legs, popliteal spaces, and inner sides of the thighs. But other parts may be also affected. The itching is apt to be most intense at night, commencing immediately upon undressing, and persisting through a longer or shorter portion of the night.

Dr. Duhring has been unable to find any previous description of this disorder, and is of the opinion that it cannot be universally prevalent. No mention is made of it by the English or German writers. From a number of cases noted in hospital, and from his observations in private practice, Dr. D. thinks that about one-twentieth of the population in Philadelphia suffer during the season of its prevalence from this form of pruritus. It was found to occur quite independently of changes in clothing, usually made at this time, the degree of cleanliness of the individual, pediculi, or other external irritation. Its constant occurrence at the beginning of the cold weather suggests some ætiological connection.

The treatment recommended is only palliative. A warm bath on going to bed was found to somewhat allay the irritation, and when the skin became very irritable from scratching, much benefit resulted from use of the alkaline bath. In addition, all irritating articles of wearing-apparel are to be avoided, both by day and by night.

ACTION OF THE BROMIDE OF POTASSIUM ON THE SKIN.—Dr. Neumann, of Vienna, has recently had an opportunity of examining a portion of skin taken from a child that had an eruption upon its body, which appeared to have been produced by taking large doses of the bromide of potassium. Three hundred and sixty-one grains had been given to arrest convulsions, and after two hundred and fifty had been taken the peculiar rash appeared.

The result of microscopic examination showed that a series of anatomical changes had taken place in the skin, and especially in the glandular structures. The hair-follicles were chiefly affected, the hair-sacs and sweat-glands in a less degree. In the early stages there was an increase in the number of the cells lining the glands, and the interior was occupied by new cells, smegma, and pus. In more advanced stages the cells of the interior were mostly shrivelled, and the glands were dilated, while a layer of young and succulent cells covered the walls.

There was also an increase of cells in the cutis, enlargement of the papillæ, with an uneven surface of the epidermis; but these appearances appeared to be secondary to the above mentioned. The author concludes that the bromide of potassium is excreted through the glands, which are thereby thrown into a state of inflammation, which is accompanied by a development of new cell elements.—*Wien. Med. Woch.*, 49, 1873.

THE RELATIONS BETWEEN BACTERIA AND DISEASE.—Dr. Hiller, of Minden, has performed a large number of experiments upon the lower animals, with the view of determining the following questions: 1. Do bacteria possess the property of exciting inflammation when they are present in living tissue, or if in the blood do they cause fever? 2. Can bacteria multiply in living tissue? 3. Do they have the capacity of penetrating living organs?

Rabbits were first selected for experiment, and in-

jections were made into the subcutaneous tissue, muscles, and veins. The fluid contained fungi in different grades of development and bacteria of different sorts, all obtained from various kinds of decomposing substances. The material in twenty-nine instances was injected under the skin, and into the muscles of the thigh, and in nine instances into either the ear or jugular vein. At the expiration of two months the animals were all alive, and never exhibited at any time symptoms of inflammation, abscess, or fever, or any other indications of general disturbance. It is true that on the first day following the injection the temperature rose, but the variation did not exceed two degrees (Fahr.) During the first forty-eight hours the temperature was noted every two hours, and then three or four times daily for the following six days. In three or four cases there was a small elevation in the skin the size of a barley-corn; but it seemed to be indolent and was gradually absorbed, and there was no further evidence of inflammation.

On the third day some portions of the skin were cut out, and after considerable search some masses of shrivelled bacteria were discovered; but in similar pieces that were examined on the eighth day, no bacteria could be found.

In cases where these fungi were injected into the vessels they were found during the first day, but even then they had no active independent motion, and the blood seemed in other respects normal. When blood was removed from the body, and as long as it was protected from drying, the bacteria multiplied very rapidly under the form of very simple round bodies. In the blood-currents of the body, though found at first, they gradually disappeared, and finally could not be detected at all. It would seem, too, that these investigations have furnished conclusive proof that bacteria, *of themselves*, do not cause septic infection, for not one of the animals that were employed had any symptoms of septicæmia, even after a lapse of three months.

As the result of further studies Dr. Hiller has reached the following conclusions:

1. The development and increase of these fungi can only take place in putrid matter, or in such as is incapable of any further independent action and holding the relation of inert matter to the living body. To this class of substances belong pus, mucus, serous exudations, extravasated blood, and urine.

2. It is true that occasionally in health, but generally where some diseased process is at work, as necrosis, inflammation, and formation of pus, vegetable organisms can find their way into the nutritive currents of the body. In cases where general disturbance of the system ensues, it should be regarded as the result of the products of inflammation and decomposition which have been absorbed with the bacteria.

3. The actual presence of bacteria in the vessels has no influence upon health. They neither multiply nor do they have any septic influence. At the moment of death, however, when the blood is no longer in motion, and when the vital energy has ceased, they may develop and multiply very rapidly. The same is true when they are caught up by the circulation and brought into immediate connection with any inert material, such as presents the conditions requisite for their growth, viz., moisture, warmth, and a nitrogenous character. This will account for their presence in pyæmic abscesses.

4. From these facts it would appear that the post-mortem appearances of bacteria in the body furnish no evidence that these organisms necessarily existed there during life. Their true life seems to commence only when the matter with which they are brought

into contact has ceased to live.—*Ally. Med. Central-Ztg.*, 2, 1874.

FATTY DEGENERATION OF THE HEART IN WOMEN DYING OF SYNCOPE SOON AFTER DELIVERY.—In the 18th No. of Guy's Hospital Reports for 1873, Dr. Phillips gives his experience in five cases of sudden death in puerperal women. In almost every instance there had been some irregularity in the action of the heart either during confinement or pregnancy. Cases of hemorrhage from placenta prævia were carefully excluded. The ages of the patients fell between 27 and 40, all were multiparæ, and death was sudden and painless. They had sat up in bed a few hours after delivery, when syncope ensued, from which they never rallied. Some had lost a slight amount of blood during delivery, and others had complained of shortness of breath, or had cyanotic discoloration of the face. At the post-mortem examination two were found to have old pleuritic adhesions, one had emphysema, but in the others the lungs were unaffected. It was noticeable that the cavities of the heart were free from clots; in fact, they were either empty or contained only a small amount of fluid-blood. The microscope, however, showed that in each instance there was fatty degeneration of the muscular tissue of the heart.—*Schmidt's Jahr.*, 9, 1873.

GASTROTOMY FOR UTERINE TUMORS.—M. Boinet (*Gaz. Hebdom.*, Nos. 8, 13, 16, 23, 28 and 29) endeavors to show that this operation should be rejected whenever the fibrous tumor is sessile, and especially when it is necessary to remove the uterus wholly or in part. The following are the conclusions to be drawn from this long memoir: In fourteen gastrotomies, performed by surgeons who thought they had to deal with ovarian cysts, fibrous tumors, more or less attacked by the bistoury or trocar, were left *in situ*, and the operation was abandoned. In spite of this nine women recovered; five died. Of twenty-three cases of extirpation of fibrous or fibro-cystic tumors, multilocular cysts, the uterus being left in its place, we must distinguish the cases of pedunculated tumors, which alone gave eight cures and five deaths, from the cases of sessile or interstitial tumors, ten of which gave ten deaths. Finally, forty-two total extirpations of tumor and womb gave thirty-two deaths and ten recoveries. In these three categories hemorrhage is the most frequent cause of death; and next to that peritonitis. Boinet concludes by giving practical advice concerning the performance of the operation, which does not differ much from ovariectomy.—*Br. Med. Jour.*, Jan. 3.

EXTIRPATION OF THE ENTIRE LARYNX.—This operation, which is probably the first that has ever been performed by any surgeon, was successfully carried out by Billroth on the 31st of December, 1873.

The patient, a man 40 years of age, had repeatedly consulted Dr. Stoerk, of Vienna, for cancerous growths within the larynx. By the aid of the laryngoscope portions were removed from time to time, and the patient was greatly relieved. In the commencement of last November the mass had extended so rapidly that further operations from above were regarded as useless, and after consultation it was decided to open the larynx from without. The cavity was exposed, the growths removed, and the base thoroughly cauterized.

The patient recovered rapidly, and for a time the prospects were encouraging. Before, however, a month had elapsed, new growths were detected by the laryngoscope, and suffocative attacks became so frequent that all further operative procedure was abandoned as

hopeless, and the canula was introduced with the hopes of prolonging the patient's life a few months. At this time the vocal cords were entirely destroyed, and the larynx was entirely filled with cancerous masses. As the glands, however, were not involved, the possibility of successfully removing the entire larynx then suggested itself to Billroth, and he felt himself further justified by the fact that experiments made upon dogs by Czerny had proved the practicability of the operation. It was accordingly done, and at the latest dates the patient was doing well. He breathes easily through a canula, which was passed into the trachea. There had been little fever, and the wound was contracting and healing favorably.

If the case continues to progress well, it is proposed to substitute a larynx of vulcanized rubber in place of the one removed.—*Wien. Med. Woch.*, 2, 1874.

THE MARSH PLANT.—Dr. John Bartlett recently read before the Chicago Society of Physicians and Surgeons an elaborate paper entitled, "*On a Marsh Plant from the Mississippi Ague Bottoms, supposed to be kindred to the Genioma of Salisbury, with a consideration of its Genetic Relations to Malarial Diseases.*" Having observed a remarkable coincidence between the flourishing of this plant and malarial prevalence, Dr. Bartlett has taken the pains to study the character and development of the growth with considerable minuteness, and has presented the results of his investigations in the above paper.

The plant was found flourishing upon marshy soil, or in regions from which the water had recently subsided. It appears as a bulbous head or globe, of about one-twentieth of an inch in diameter, surmounting a slender stem or root, which is branched at its lower extremity. The globe consists of an outer, green, cellular layer, resting upon an inner, whitish layer, similar to a basement membrane, enclosing a central cavity filled with clear fluid. The root corresponds in structure with the inner layer of the globe, with which it appears continuous, and has a central canal. In process of growth the upper hemisphere of the globe collapses, making it cup-shaped. Upon the cup-shaped plants, as well as upon the soil and various objects adjacent to the plants, there now appears a sort of whitish, dust-like deposit. In this deposit, according to Bartlett, exist the germs of malarial diseases. The deposit is composed of "germinal atoms," "crystalline substance," "threads and filaments," "crystalloid bodies," etc., which remain to be described. According to the botanists, Profs. Babcock and Munroe, to whom specimens were submitted, this deposit-appearance belongs to some development entirely distinct from the marsh plant, probably to some fungus parasitic to it. (According to these gentlemen the marsh plant is the *Hygrogastrum of Rabenhorst*, or the *Botrydium* of the micrographic dictionary.) Dr. Bartlett, however, finds in the deposit evidence of another phase in the marsh plant's existence. The connection is traced as follows: After the globe of the plant collapses, the cells of its outer layer elongate, burst, and give exit to small cells or spores, resembling, except in size, the parent cell. These spores next disintegrate, with the production, as they disappear, of very minute particles (less than 1-15000 of an inch), which are termed "germinal atoms." These are supposed to answer to Salisbury's "spores." The "germinal atoms" appear to have diverse destinies. Some combine in threads, which grow (in a somewhat remarkable manner) till myceliae are produced, while others agglomerate in little crystalloid masses. Meantime, from the surface of the globe, as well as from

the crystalloid bodies, shoot up little acicular crystals, surmounted by minute glass-like bulbs. These, it is surmised, furnish the pollen. The next step is the appearance upon the crystalloid bodies of little green "points of verdification," which finally result in the production of cells or spores resembling the cells of the original plant. The cycle of development is thus completed.

During the growth of the marsh plant the atmosphere is supposed to be loaded with the germinal atoms. A glass slide suspended over the plant is soon studded with multitudes of these particles, and it is probable that they may easily be borne through the air to remote distances. A correspondence between ague and "ague plants," as to localities, etc., is shown in a tabular form.

During the pursuance of his investigations, being constantly exposed to the malarial influence, the author found the germinal particles abundant in his blood, and suffered simultaneously with symptoms of remittent fever. In the urine the atoms appeared after five minutes, and rapidly formed crystalloid bodies and crystalline filaments.

Considerable space is devoted to a consideration of the objections urged by Dr. Horatio Wood and others, to Salsbury's germinal theory. Dr. Bartlett thinks that many of these lose their force in view of the new facts which he has elicited. In conclusion, the writer desires "such co-operation from other observers as may insure an early solution of the question at issue."—*The Chicago Med. Jour.*, January, 1874.

OVARIOTOMY.—Dr. George A. Mursick reports a case of ovariectomy, in the *Am. Jour. of the Med. Sciences*, Jan., 1874, which presents the following points of practical interest: 1. The removal of the tumor by enucleation. 2. The establishment of free drainage per vaginam by the seton. 3. The administration of medicine by subcutaneous injection, in consequence of excessive gastric irritability. 4. The support of the patient by nutritive enemata. 5. The value of quinia in the prevention and cure of septicæmia.

The tumor was multilocular and proliferous, and was largely adherent posteriorly and in the region of the pelvis. After evacuating seven cysts the tumor was removed by detaching it from its adhesions and vascular investment by means of the fingers and the handle of a scalpel. No hemorrhage occurred and no ligatures were required. To establish a free drainage Douglas's cul-de-sac was punctured and several strands of ligature silk were passed into the abdominal cavity. The ends which emerged at the vagina and at the lower angle of the abdominal wound were tied together. On the third day the condition becoming bad with retching and vomiting, so that neither food nor medicine could be retained in the stomach, rectal enemata were resorted to, and four grains of sulphate of quinine, with one quarter of a grain of sulphate of morphia, were injected subcutaneously every six hours. Improvement began at the beginning of the second week, with ultimate complete recovery.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, March 2, 1874.

THE EFFICIENCY OF THE ARMY MEDICAL STAFF.

WE understand that the Military Committee of Congress are now perfecting a bill to reduce the army by seven regiments. This fact is a significant one to every medical man who has an interest in the well-being and prosperity of the Medical Staff. The question which it suggests is, What will be done with army surgeons? what changes will be made corresponding to this proposed reduction of the line, and what effect will they have upon the usefulness of our arm of the service?

In any event, conjecture of what may be, can be the only point upon which can turn a suggestion as to what should be. We may presume that the medical staff will with the others come in for its share of reduction, and having presumed thus much, we take another step by asking ourselves the questions, how can this be done, and why should it be done?

The present number of army medical officers available for duty at military posts may be estimated in round numbers at one hundred and thirty, in addition to which there are about one hundred and forty-five contract surgeons, making in all about two hundred and seventy-five physicians employed, besides medical directors. In the first place the scarcity of medical officers is a deplorable fact the proofs of which have been repeatedly given by references to the reports of the Surgeon General. Why this lack of numbers exists we do not now propose to explain, but shall be content to make the assertion that such is the case. Even with the employment of physicians by contract there is a bare sufficiency of medical men for the care of the established military posts. The number of men in any given post does not settle the question whether there shall or shall not be an army surgeon to

care for them; the reduction of the actual force forms no element in the discussion of the practicability of reducing the existing medical staff; five men on a post have as much right to be cared for in a medical way as a thousand. So long, then, as the military posts remain the same, the medical staff should continue the same in the number of its members. If it be decided that the existing medical posts can be reduced, the committee may then take upon itself the responsibility of making an equivalent reduction of the medical corps, and not till then. If, for instance, one-sixth of the posts are abandoned, then one-sixth of the surgeons could be dispensed with, or forty-six, leaving two hundred and thirty required. Even if we were to allow of the small reduction of one-tenth the number of posts, which, according to our best military authorities, is not an allowable estimate, the medical corps of the army, if it were full, would not be sufficient.

Even if this reduction of the number of military posts were admissible, we contend that the medical staff should not be reduced. There are two corps in the army which can do good service to the government and the country in time of peace in work not directly connected with the army; we refer to the Corps of Engineers and Surgeons. Of the special services of the latter, in this respect, we are best prepared to speak. The surest promise of what can be done, is the fact of what has been done by army surgeons, even while attending to their required duties. In this connection we need not go beyond a reference to the contributions of the valuable specimens to the army medical museum which represent an aggregate of gratuitous work on the part of the army medical officers as unprecedented in amount as it is invaluable in scientific interest. But this is not an isolated instance of what can be done by competent men, and if such can be accomplished as incidental to their legitimate duties, what may we not expect from the same class of men when they have the requisites of encouragement, and fuller opportunities to cultivate the special talent which they may possess. We have individual examples of what can be accomplished when suitable and special details are made for scientific work. The brilliant results growing out of the study of the microscope and the demonstration of the utility of micro-photography as a means of truthfully disseminating accurate scientific data have, in connection with the work in the army museum, accomplished wonders for American medicine. The masterly compilation of the Medical and Surgical History of the War is another proof of the wisdom of utilizing the medical staff; and the library of the Surgeon-General's office, destined to be the national medical library, is still another instance of what may be done in another direction by a talented and indefatigable army officer. The gentlemen who have performed these labors belong to a class of men of whom the American medical profession are especially proud, and who in their respective spheres are capable

of conferring a lasting benefit upon our science everywhere. There are many others who could work in other special fields with equal credit to themselves, with equal benefit to medicine, and with equal profit to the Government.

We do not, however, wish to go to extremes in urging claims of special scientific work to the exclusion of the legitimate army duties, as such would not be strictly in keeping with the direct requirements of the service, but merely desire to show what may be done by army surgeons in times of peace, and how that portion of their time not consumed in the routine of strictly official duties, can be utilized by an intelligent and discriminative direction of their special tastes in the different departments of scientific investigations.

Not only should the Government retain such men in service, but should give them every encouragement. If it fails to do so it shoulders the heavy responsibility of denying to scientific medicine the opportunity of working up the vast stores of material now in its possession, of systematizing accumulated experience, and of obtaining and distributing information of incalculable benefit to suffering humanity. The good which will obtain from such labors will be only proportionate to the enormous scale on which they can be carried on. The profession, it is true, can alone form an estimate of the ultimate results of such work, and can alone judge of its necessity, but it cannot in justice to its own interests be content in merely hoping for the best. The time has come when its influence must be exerted in the proper direction to secure the desired end. Unless there be some better reason than the saving of a few dollars and cents, or the actual reduction of the number of our military posts, the medical force should not only remain as it is, but every effort should be made and every influence exerted with the different members of Congress to increase the efficiency of the staff. In no better way could the latter be accomplished than by favoring the Army Rank Bill founded on the memorial of the American Medical Association. The contemplation of the possibility of success is by no means a forlorn hope if there be a determination on the part of the profession throughout the country equal to that which characterized its successful working for the passage of the Naval Staff Rank bill two years ago. The army surgeons only ask that the equivalent rank to that already possessed by the navy surgeons be given them, and if there is any weight in the argument of precedence, the result, in spite of the cry for economy, would seem to be a foregone conclusion.

THE EXPOSURE OF QUACKERY.

We have repeatedly called the attention of the secular press to the bad influences which may arise from the admission of quack advertisements in their columns—a practice which, on its face, appears, to the uninitiated at least, to give the weight of an authority to the statements therein contained. Very many of these

periodicals go still further, and in the very columns devoted to morals and religion have the audacity to insert bogus letters of endorsement for these pretenders, and even with an editorial recommendation call more particular attention to the item. In view of this deplorable state of affairs it is certainly refreshing and encouraging to know that there is at least one respectable journal in New York, *The American Agriculturist*, which not only dares to reject quack advertisements, but which takes the pains to expose quackery in every shape. One of the fraternity of pretenders, the proprietor of the so-called "Golden Remedies," whose business was injured thereby, recently brought a suit against the publishers of that journal, claiming twenty-five thousand dollars damages. The defence set up was to the effect that the remedies were worthless; that the plaintiff was not an educated medical man; that he was a quack, a swindler, and an impostor. In the examination it was shown that the plaintiff's title was only an assumed one. The said plaintiff refused, on trial, to state the ingredients of the different compounds further than that they were secret compounds possessing great medicinal virtues.

A motion was made before a Judge at Chambers, by defendants' counsel, to strike out the complaint, which was granted, and the suit vacated with costs. An appeal was then made to the General Term, where the decision was maintained. Judge Davis, in delivering an opinion, made the following important statement:

"It is impossible to read the vulgar, and in many respects shameful, assertions and instructions that accompany the compounds of plaintiff, without being struck with the vileness of the impostures. That he can bring an action of libel for injury alleged to be done to his trade in his medicines by denouncing them as arrant quackery, and at the same time protect himself against exposure by claiming them to be valuable secrets, is a proposition that cannot be maintained. *Byrn vs. Judd*, 11 Abbott, New Series; 11 New York, 347, New Series. In the laudable exposure of such 'humbugs' as the pretended medicine of plaintiff and others, the defendants take upon themselves great risks, and subject themselves to the annoyance of suits; but I think they are not exposed to any danger that courts will interpose any shield for the protection of parties guilty of fraud and deception of the public. If the plaintiff did not choose to try the question of the true character of his 'Golden Remedies,' he should have kept out of a court of justice."

The American Agriculturist deserves the thanks of the profession and the public for the stand which it has taken in this matter, and we hope it will be encouraged to proceed in its good work, and ever be an example of what determination in the cause of truth and justice can accomplish. One explanation for the fearlessness of the attacks upon quackery by this journal is, that it has upon its staff a thoroughly educated medical man, who is determined to discharge his responsible

duties to his many readers. It would be well if every responsible paper had such a conscientious worker upon its staff, one who could at least be allowed to sit in judgment upon the merits of all quack advertisements which might be offered. Until some such plan can be adopted the press at large can never free itself from the most pernicious of all systems of humbuggery.

Reviews and Notices of Books.

DISEASES OF THE STOMACH. By WILSON FOX, M.D. Third Edition of the "Diagnosis and Treatment of Dyspepsia." Revised and Enlarged. Macmillan and Co., London and New York.

We never open a book of this kind without a feeling of regret at the existence of two incompatible necessities of medical life. The first is the necessity for analyzing phenomena to their ultimate elements, and of establishing on an exact, incontrovertible basis, by means of personal observation and experiment, every assertion that may be made in regard to disease or therapeutics. With this exclusively in mind, no author would pretend to publish anything, except in positive elucidation of some of the many pathological conditions that for years have been described, discussed, and classified, in medical literature, and whose history yet remains incomplete. Could every one remember all that had been written on diseases of the stomach, even within the last twenty years, he would have no occasion to consult this attractive little volume by Dr. Fox, for in that he will find little which has not been said before, somewhere, and in no inaccessible locality. But the second necessity of the medical practitioner, and which too often becomes the first, is that of possessing, in compact and portable form, the statement of the principal facts and doctrines, by which he must be guided in his daily work, and for such purpose books like these, appearing in slightly modified form every few years, are really useful, although their use is limited, and their indications have often been fulfilled before. The classification of subjects in Dr. Fox's volume is good. The first part is devoted to a description and analysis of the principal symptoms that occur in the course of stomach affections, as flatulence, acidity, pain, vomiting, etc. In relation to the first, the author discusses and rejects the theory of secretion of gas from the blood, either into the stomach or intestines, although this theory is still admitted by Bédard. He ascribes the presence of an excessive quantity of gas in the stomach to one of two causes,—to the ingestion of air, by relaxation of the cardiac orifice; or to the fermentation of solid and liquid substances whose digestion has been arrested. He describes rather cursorily the consequences of the tympanitic distension of the stomach, but omits to mention the more alarming effects, as syncope, or even sudden death, which may follow with excessive distention, especially in patients whose heart is in any way diseased. The mechanism of vomiting is very well discussed. In regard to epigastric pain, the writer dwells on the importance of distinguishing between pain seated in the stomach or myalgia. Briquet long ago pointed out the frequency of the latter in hysterical affections. The distinction may often be made by pressing upon the insertion of the recti or oblique abdominis, when the pain elicited is as severe as at the epigastrium. Romberg's opinion is quoted, that the real neuralgia of the stomach which is accompanied by a sense of faintness, depends on the solar plexus, while

neuralgia of the vagus is rather marked by perversions of appetite. But of all aberrations from the healthy functions of the stomach, indigestion is the most important, and is manifested both by phenomena which are the primary results of imperfect changes in food, and by others which are the more remote effects of these. It is these latter which so frequently give rise to errors in diagnosis,—and they are very well classified by the author into—

Disturbances of the nervous system, including neuralgia, muscular weakness, headache, loss of memory, hypochondriasis, hysteria, even convulsions, etc.

Alterations in urinary secretions, with excess of water or of urea, laticerous sediments, variations of reaction of abnormal contents, as albumen, sugar, cystine, oxalates.

Disturbances in generative organs, as perverted menstruation, leucorrhœa in the female, impotence, spermatorrhœa in the male.

Alterations in the skin, febrile heat or suppression of perspiration, coldness, earthy yellow tint,—various eruptions, as erythema, ceynenia, herpes, acne impetigo, lichen, urticaria.

Alterations in circulation, palpitations, cardiac intermitteces, excitability of pulse.

Alterations in respiration, dyspnoea, cough, asthma.

Alterations in general nutrition, anaemia, emaciation, grayness or loss of hair, caries of teeth, incurvation of nails, inflammation of mucous membranes, development of hereditary tendencies to gout, rheumatism, venal, or pulmonary affections. This part is one of the most useful in the book.

The second part of the book is devoted to the consideration of special diseases of the stomach. The several chapters are concisely and clearly written,—offering nothing especially new or original, but resuming very well what has been already said or demonstrated. Separate chapters are consecrated to atonic dyspepsia, neuroses, acute catarrh, chronic catarrh, ulcer, cancer, hemorrhage, hypertrophy, stricture of cardiac or pyloric orifices, dilatation, softening, perforation, rupture, tubercle. The distinctions between atonic dyspepsia and the various neuroses of the stomach are very well exposed,—the author premising at the outset that many impairments of digestion due to nervous derangement really present no symptoms but those of atonic dyspepsia. The erosions of mucous membrane, characteristic of chronic catarrh, are well described, and their microscopical appearances figured in two lithographic plates. The separate chapter devoted to hemorrhage is superfluous, since, as the author remarks, this is only a symptom of some pathological condition otherwise classified. The chapter on cancer alone contains a list of bibliographical references and some statistics in regard to frequency of the disease. The pathological anatomy is, however, rather superficial, and the affirmation that cancer, "whether schirrous or medullary, almost invariably originates in the submucous tissue," must be considered as much too absolute in the presence of the still-pending controversy on its epithelial origin. (See Thiersch, also the memoir of Walderger, *Arch. Virch.*, June, 1872.)

A SYSTEM OF MIDWIFERY, INCLUDING THE DISEASES OF PREGNANCY AND THE PUERPERAL STATE. By WILLIAM LEISHMAN, M.D., Professor of Midwifery in the University of Glasgow. Late Vice-President of the London Obstetrical Society, etc., etc. With 182 illustrations. Philadelphia: Henry C. Lea. 1873. 8vo, pp. 715.

THIS handsome volume was given to the profession some three months since, and has received extended

and favorable notice in several of the leading journals.

It proposes to offer to practitioners and students "A Complete System of the Midwifery of the Present Day," and well redeems the promise.

Where so much is attempted in the compass of a single volume, it is unavoidable that some topics should be rather cursorily treated.

Dr. Leishman's name has been associated with researches into the mechanism of labor, by a monograph published in 1864, in which he controverted, ably, some of Naegele's classical propositions upon that subject.

His views have since received the support of distinguished British obstetricians, and are fully elaborated in the present volume.

In all that relates to the subject of labor, the teaching is admirably clear, concise, and practical, representing not alone British practice, but the contributions of Continental and American schools.

The chapters upon the Development of the Ovum give but an outline of the subject, and do not contain some of the most recent studies in embryology.

From the chapter on the Induction of Premature Labor, otherwise excellent, we notice the omission of the use of the elastic catheter, and the Molesworth dilator, which are in favor among us.

From the discussion of inversion of the uterus, we infer that the author would condemn to ablation some of the cases of long standing, which have been successfully reduced by American operators.

It is several years since we have had a "system" of midwifery from British sources. The accumulated observations of this period are given us in the present volume, which is, therefore, as timely as it is valuable. We think it very well suited for a text-book, as well as a manual of reference, to which its complete index conduces.

The typography is very fair, and the illustrations abundant, and, in some cases, new to English readers.

Reports of Societies.

NEW YORK JOURNAL AND LIBRARY ASSOCIATION.

Stated Meeting, November 28, 1873.

DR. J. C. PETERS, PRESIDENT, in the Chair.

DISCUSSION ON DR. LINCOLN'S PAPER.

DR. POST was of the opinion that when the effusion on the mucous membrane was serous, scarification was sufficient to give relief; but when the material was of a plastic nature, tracheotomy might be called for, and only then.

DR. ROBINSON had employed scarification when oedema in the larynx was present, and obtained no relief. He does not believe that any benefit is to be derived from it, because the exudation is generally plastic, and not serous. He was opposed to the use of nitrate of silver, because it was liable to provoke spasm of the glottis, and spasm of the glottis, in the last stages of the affection, might of itself prove fatal, although he could bring no facts to substantiate this in a positive way. If it is used for its astringent effects simply, it is no better than many other astringents. He doubted very much whether any local applications were of benefit in the advanced stages, unless it was morphia. That may lessen pain somewhat. He believed

that phthisical influences should be regarded as the foundation of the disease, and that tubercles might have been found in most cases if close examination had been made.

DR. BURRALL inquired whether reference was made to applications of nitrate of silver by means of a brush or by spray, for the effects are entirely different. Comparatively weak solutions will produce irritation when applied with a brush, whereas very strong solutions can be used by spray and produce but comparatively little irritation.

DR. ROBINSON replied that he had reference more particularly to the use of the brush. In the spray we use nothing like a strong solution as a general thing.

DR. FARNHAM has used solution of nitrate of silver from 5-10 grs. to the ounce with brush or sponge, before spray was introduced, and never without producing severe spasm. He has used with the spray solutions varying from 5 to 480 grs. to the ounce, without producing anything approaching to the spasm produced by weaker solutions applied with sponge or brush.

DR. CANO mentioned two remedies which he had employed with good results, which had not been mentioned. Oil of turpentine, in oedema of larynx particularly, is more serviceable than scarification; muriate of ammonia to relieve an irritable condition of the throat.

DR. LINCOLN said that it was better to employ strong rather than weak solutions of nitrate of silver, if pain is referred to. Strong solutions are much less painful.

Spray of nitrate of silver under high pressure affords a means of application which in point of convenience surpasses all others. With the instrument designed by Dr. Saas, a pressure of 30 or 35 lbs. to the sq. inch can be easily managed. The nitrate of silver acts upon the albuminous part of the membrane and coagulates it. Chloride of gold and acid nitrate of mercury act to destroy the tissues, and should be applied for specific purposes and with the greatest care.

DR. ROBINSON was certain that a strong solution of nitrate of silver would produce sloughing of the tissues, the same as acid nitrate of mercury, and that the objection to one was equally applicable to the other.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Monday Evening, January 25, 1874.

THE PRESIDENT, DR. ELLSWORTH ELIOT, in the Chair.

VICTIMS OF YELLOW FEVER.

FOLLOWING the reading of the minutes, Dr. J. Marion Sims read a memorial and offered resolutions relative to the members of the medical profession who died at Memphis of yellow fever during the late epidemic. On motion, Drs. Sims, Parker, Metcalfe, G. M. Smith, and Sands, were appointed a committee to solicit subscriptions to a fund to be used in erecting a monument to the memory of the deceased physicians.

NEW MEMBERS.

The following gentlemen, being recommended by the comitia minora, were granted certificates of membership: T. MATLACK CHEESMAN, 5 E. 27th street, a graduate in medicine at the College of Phys. and

Surg., Univ. of the State of New York, in 1859; J. VARNUM MOTT, 99 Park ave., a graduate in medicine at the Col. of Phys. and Surg., Med. Dept. of Columbia Col., in 1872; HENRY T. STRONG, 130 W. 129th street, a graduate in medicine at the Col. of Phys. and Surg., Med. Dep. of Columbia Col., in 1868; HENRY S. SWAN, 147 W. 45th street, a graduate in medicine at the Col. of Phys. and Surg., Med. Dep. of Columbia Col., in 1871; ROBERT F. WEIR, 19 E. 32d street, a graduate in medicine at the Col. of Phys. and Surg., Univ. of the State of N. Y., in 1859; CLAUDE G. STANLEY, 158 E. 28th street, a graduate in medicine at Bellevue Hosp. Med. Col., in 1870; GEO. H. FOX, 111 W. 34th street, a graduate in medicine at the Univ. of Pennsylvania, at Philadelphia, in 1869; GEOFFREY R. BOURKE, 40 Leroy street, a licentiate of the Royal College of Surgeons, Ireland, in 1869, licentiate of King's and Queen's College of Phys., Ireland, in 1869; and GEORGE W. HOLMES, 368 Broome street, a graduate in medicine at the Univ. of Mich., in 1872.

DECEASED MEMBERS.

The PRESIDENT announced the death of DR. JOSEPH SMITH PERRY, a licentiate of the Ulster Co. Med. Soc., and a member of this Society since 1828, who died in this city, January 3d ultimo, in the 89th year of his age.

MISCELLANEOUS BUSINESS.

The petition of Dr. F. R. Newman, that the Society recommend him to the State Medical Society as a suitable person to receive the honorary degree of Doctor in Medicine, was granted.

The SECRETARY read a report from the comitia minora, accompanied by a communication from Dr. Prout, of Kings County, relative to a change in the mode of electing permanent members to the State Medical Society, as follows:

The committee recommend that this County Society recommend the following to the State Society, with the request that proper steps be taken to insure its enactment:

"An act to regulate the manner of electing permanent members in the Medical Society of the State of New York:

"The people of the State of New York, represented in Senate and Assembly, do enact as follows:

"SECTION 1. It shall and may be lawful for the Medical Society of this State to elect annually sixteen permanent members, in such manner as said Society may from time to time determine by its by-laws, who shall be chosen from the thirty-two senatorial districts now existing, in alternation, by even and odd numbers. The members so elected shall reside in the districts from which they may be chosen.

"Provided, however, that when a county shall contain two or more districts, residence shall be restricted only to the including county.

"SEC. 2. All acts or parts of acts inconsistent with this act are hereby repealed.

"SEC. 3. This act shall take effect immediately."

The PRESIDENT explained that since 1836, when the proportion of regular members was regulated by legislative enactment, and made to bear the same proportion to the population that existed in the senatorial representation, the population of the State and its senatorial representation had greatly increased, and instead of electing eight permanent members we should have sixteen.

The district to which New York and Kings County belong had already forty-eight on the list of those who are eligible for permanent membership, and at

the rate of two annually, it would require twenty-four years to exhaust the list, even if no additions were to be made.

DRS. CHADSEY and VAN KLEEK made a few remarks upon the subject, the former advocating the change proposed, the latter thinking that the interests of the State Society required that, whereas the distribution of appointments should be characterized by fairness towards all the districts, the Society should be restricted to its present limits as regards the number of members.

On motion, the communication was adopted as expressive of the views of this Society.

DR. VAN KLEEK offered resolutions regarding Dr. Stillwell, deceased, which were adopted.

The PRESIDENT announced the presence of DRS. FITZGERALD, of Salem, Mass., and GATES, of Concord, N. H.

REPORT OF COMMITTEE.

DR. A. B. JUDSON read, in the absence of Dr. Russell, the Report of the Committee on Diseases.

By this it appears that the grand total of deaths in New York, in the year ending Dec. 31, 1873, was 29,054, against 32,647 in 1872, and an average in the preceding five years of 27,370.8. These 29,000 deaths were divided among the five classes as follows:

Zymotic, 9,593; constitutional, 6,293; local, 10,154; developmental, 1,883; by violence, 1,161; diarrheal diseases in children under five years of age caused 3,634 deaths against 4,680 in 1872, and an average of 3,487 for the preceding five years; diphtheria caused 1,151 deaths against an average of 319; membranous croup, 732, against an average of 477.4; small-pox, 117 deaths, against 929 in 1872 and 805 in 1871; measles, 306 deaths, the average for five years preceding being 379.4; from scarlatina came 1,045 deaths, against an average of 916. In the past six years small-pox caused 2,373 deaths; measles, 2,202, and scarlatina, 5,628. Consumption caused, in 1873, 4,134 deaths. There were 117 suicides, and 155 deaths from drowning. In the institutions were 4,755 deaths. Of the total mortality there were 14,128 deaths of children under five years old; 1,495 of persons over seventy. The following cases of contagious diseases were reported to the Sanitary Bureau: Typhus fever, 83; typhoid fever, 371; scarlet fever, 2,747; measles, 1,061; diphtheria, 1,591; small-pox, 330.

DRAINAGE AND SEWERAGE.

DR. MOREAU MORRIS, Chairman of the Committee on Hygiene, then read the report of the Committee, which was submitted for transmission to the State Society.

The Doctor first explained the difference between the terms drainage and sewerage, and then proceeded to say that in the settlement of an individual or community upon any new territory, the question of its drainage is of the first importance. Sewerage may also become a subject of consideration. The continual health of the individual, as of the community, depends upon the proper drainage of the natural soil, while the question of sewerage awaits the force of circumstances, without, perhaps, being indispensable to continued health. A water-saturated soil cannot be dwelt upon and perfect health be maintained; therefore proper drainage becomes a vital necessity to its permanent occupancy. Drainage is that system or method by which the unnecessary or superabundant water may be removed from the soil which has or may become saturated. It may be of natural or artificial means, or by a combination of both. The natural topography may be such as

to require but little aid from art in perfecting the drainage of a section of country, while, on the other hand, art alone may be able to so drain it as to render it habitually healthy. Therefore, among the first conditions presented in the selection of a site for human occupancy is involved a study of its topography, and, incidental thereto, of its substratum or geological formation. Natural water-courses, assisted by art, often afford the best means for draining saturated soil, and should never be lost sight of in any artificial adaptation. Too often an ignorant interference with nature's provision has brought untold misery upon future residents. "Water will not flow up-hill," and "always finds its lowest level," and unless it finds an outlet, natural or artificial, will saturate adjacent soil.

A lamentable example of this occurred a few years ago at Seventy-fifth street and Third avenue, where some builders permanently obstructed a natural water-course, and caused the submergence and saturation of more than fifteen acres of soil that had been drained by it previously. The result was, that almost every dwelling for several blocks around suffered with malarial poison, from which many deaths occurred. The ignorant but popular idea that filling in earth upon saturated soil precludes the necessity of deep drainage has produced permanent evils that, at the present day, it is almost impossible to remedy. No statistics, illustrations, or arguments are needed in the present day to convince the medical profession of the unhealthiness of saturated soil for human habitation. A very large proportion of human ailments can be traced directly or indirectly to its influence. Even a water-saturated atmosphere directly tends to increase mortality among the enfeebled, as we have had abundant evidence during the recent long-continued and dense fogs, by the mortuary statistics of this county. While mortuary tables exhibit only a small portion of the influences of water-saturation, we should not forget the sickness and impaired health which have been the direct and indirect consequences.

Respecting the causes which are in operation by which streams are made the source of disease, may be enumerated the grading streets and avenues across the line of natural drainage without making provision by culverts for the passage of water in its natural bed; filling up boulevards with refuse and garbage, causing a permanent deposit of decomposing organic matter, which for all time remains to add a fetid character to the exhalations which arise; and making use of natural streams for sewerage of all kinds.

Gen. E. L. Viele, in a report to the Board of Health, in 1870, gives a notable instance of this in one of our public hygienic institutions, the Bloomingdale Lunatic Asylum, situated upon high ground, between Tenth and Eleventh avenues, near the Hudson River. A stream near the institution has been used as a receptacle for all its liquid refuse. This stream passes along the line of Tenth avenue to One hundred and twenty-fifth street, where it meets with low, swampy ground, empties into a pond at the junction of One hundred and twenty-fifth street and Tenth avenue. In the neighborhood of this pond fevers of a malignant type have prevailed for years. Hardly a person within the radius of half a mile has escaped the deleterious effects. Other instances he enumerates equally striking in their direct effects upon life. In laying out railroads and highways, canals or other internal improvements, through any section of country, natural drainage-streams are constantly obstructed, and stagnant ponds formed, which inevitably produce evil effects. In the upper portion of the county lying above Fifty-ninth street, for many years past, fevers, inter-

mittent, remittent, and typhoid, have been constantly prevalent.

With recent improvements in drainage and sewerage, already these forms of disease are becoming less prevalent. Yet so many undrained sections still exist, in connection with acres of "soil-saturated areas," that some years must elapse before the sources of these fevers will be entirely removed. The report concluded by pointing out the fact that the Health Commissioners permit the filling in of all the marshy lands of Harlem Flats with the refuse garbage of the city, and concurs with the opinion of the State Committee that the work of primary importance is drainage.

Dr. A. N. BELL, of Brooklyn, Chairman of the Committee of the State Medical Society, expressed his gratification with Dr. Morris's paper. The committee had received twenty-four responses from County Medical Societies, and three or four reports have been made, while more are expected soon. Dr. Bell then went on to speak of drainage in Brooklyn and in Kings County the condition of which, he said, was much worse than that of New York. In that county are over 100,000 acres of deficiently drained land, and careful investigation shows that one-fifth of the total mortality in the city of Brooklyn is due to defective drainage.

Measures for draining portions of the island had been very successful, and the farmers were beginning to appreciate the value of the improvement, as an agricultural as well as a sanitary measure. The Doctor mentioned that not far from Brooklyn, where some time ago a woman committed suicide by drowning in seven feet of water, flourishing farms now existed.

An obstacle to the natural drainage of some portions of Kings County was the presence below the soil of a hard-pan which held the surface-water in basins. In the Prospect Park this trouble had been removed by making perforations at the lowest points in these hollows, so that the water could pass through to the stratum of earth beneath.

He further referred to the insalubrious character of the artificial ponds caused by the so-called *city improvements*, and called attention to the "Drainage Reports" of the Board of Public Works, which had no evidence of anything whatever in the way of drainage having been done, and related entirely to sewerage.

Dr. GATES, of Concord, was invited to speak on the subject, and said that in his locality the natural drainage of the land and the sandy nature of the soil were such that he had little opportunity of knowing much by experience of the effects of soil-saturation. A system of drainage, however, was being undertaken in Concord, which, with but little expense, would make it one of the healthiest cities in the country.

Dr. CARO spoke of the very great changes which had resulted from improvements in the drainage of Italian cities, mentioning Palermo and Rome as examples, in which malarial fevers had been greatly diminished, both in frequency and intensity, as a result of improvements in drainage during the past three years.

The paper was accepted, and directed to be forwarded, as the report of the committee, to the Committee of the State Society.

NEW INSTRUMENTS.

Dr. ROBERT NEWMAN exhibited a galvanocautery battery, made by Mr. Drescher, and illustrated its power of heating an iron or platinum wire for an indefinite period.

Dr. JACOB remarked that, although the battery was an excellent one, the credit of its invention was due to Stehrer, and not to Mr. Drescher.

DR. BEARD acknowledged that Stöhrer was the first to adapt this form of battery to the wants of the profession, but that Walker, of London, was the one who suggested, about 1855, the use of carbon instead of platinum.

ARMY MEDICAL STAFF RANK.

DR. J. C. PETERS moved the adoption of the resolutions passed by the Academy of Medicine at its recent meeting, relative to the rank of army medical officers, which motion was carried. He then moved the adoption, by this Society, of the resolutions of the Pathological Society relative to the congressional appropriation for the maintenance of the Army Medical Museum and Library. Carried.

The PRESIDENT then announced the subjects of the papers to be read at the next meeting, and the Society adjourned.

Correspondence.

THE SIAMESE TWINS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Last night the remains of the SIAMESE TWINS were exhibited to the Fellows of the College of Physicians, and the nature of their intercommunications, as far as yet determined, explained by Drs. Wm. H. Pancoast and Harrison Allen. I endeavored to obtain permission from the meeting to have THE MEDICAL RECORD furnished with an abstract of the result of the autopsy, or "report of the commission," as it is called, similar to that which will appear in this week's *Medical Times*, but it was ungraciously refused. The Editor of the *Times*, however, has promised to send you an advanced copy of his own report of the meeting, as taken down by two professional phonographers, and you will therefore receive, in time for your next issue, a much more accurate account than I could have furnished.

The connecting medium is a band four inches in length and eight inches in circumference. The ensiform appendix of each body is continuous in this band, arching forwards in the form of a bow, an acquired configuration, doubtless, the result of their reciprocal efforts to accommodate their position side by side. In the normal condition they face each other. This ensiform connection is fibro-cartilaginous and flexible; but there is no evidence of any articulation permitting the amount of motion known to exist in life; for it is said that one of the twins could rise and cross the body of the other without awakening him from sleep. A thin, translucent section of the central portion of this band, held up to the light by Dr. Allen, appeared homogeneous, without any evidence of junction of separate processes.

The peritoneal cavity of each twin terminates in a cul-de-sac, or pouch, which crosses a similar arrangement of its fellow within the band. Each pouch crosses the middle line, and the finger passed within one of them enters the suspensory ligament of the opposite body, but the pouches are not at all connected. The cul-de-sac of Chang is double, the single cul-de-sac of Eng dipping between it. Hence, a division through any point of the band would have inevitably opened both peritoneal cavities. A nice dissection, however, would have permitted the separation of these peritoneal sacs. There are no large vessels in the band. The only actual intercommunication appears to be what Dr. Allen called a "portal continuity" between the

livers. An injection into the portal system of Chang passed into the portal system of Eng.

The livers of the twins are on the adjoining sides respectively, and are lost in an intercommunicating tissue, which may or may not contain hepatic substance. To the touch there is no evidence of liver structure; but the edges of each liver cannot be felt in a continuous line, and there is therefore a possibility of this communicating tissue having primarily been continuous with each liver, in which case some evidence will be found on minuter dissection and on microscopic examination. The umbilicus of the twins is common, and exists at the lower edge of the band, the navel being much obliterated; but there is a curious anomaly in each case, consisting of an isolated mass of fat, about the volume of a chestnut, under the peritoneum, at the point where a normal umbilicus would exist.

Posteriorly there is a large subcutaneous pouch on each side, crossing the middle line of the band, the significance of which has not yet been made out. Some of the muscular fibres of one body cross over into the other; but for the details on these points I refer you to the elaborate report prepared for the *Times*.

The thoracic viscera have not yet been examined. The report of Drs. Pancoast and Allen was merely a verbal one, and was illustrated by a number of casts and drawings. The final report will be very elaborate, and will probably be published, with chromo-lithographic illustrations, by the College or by the Smithsonian Institute, or some other liberal scientific body.

In the course of his remarks Dr. Pancoast alluded to a number of humorous incidents in the history of the twins. He stated that they never really desired to be separated except on one occasion, when, after a quarrel, they repaired to the residence of Dr. Hollingsworth for that purpose, but changed their minds before they left his office. It appears that it was "an exhibition dodge" with them to have the band examined from time to time, and to have the feasibility of separation discussed by eminent authorities in the various places they visited, the "draw" being usually immense after the announcement of one of these examinations. It certainly appears to me, though I may be an incompetent judge, that they could have been separated without great danger to life, even though the peritoneal sacs had been opened. Peritoneal sacs are opened frequently by surgeons, nowadays, without fear of fatal results.

The one body showed, in every particular, greater physical development than the other. It is the body of the temperate twin, the other one having been frequently given to intemperance, which, however, had no effect upon his brother; showing a want of essential nervous as well as vascular intercommunication. The weaker brother was dead several hours before the other was aware of it, and much of the immediate cause of his death is to be attributed to the nervous shock he experienced on realizing his own perilous condition.

After the report had been made, Dr. Jacobi, of your city, was requested to give his opinion as to the mode of conception or development of this curious twin-product; and, in a very neat address, which will probably be appended to the report in the *Times*, expressed his preference for the belief of those who considered such formations due to the simultaneous fecundation of two nuclei in one ovum, or two ova in one Graafian follicle, rather than the belief that there had been an adherence of two separate conceptions in one amnion.

While the report was being made a twin-apple was

handed round—two apples joined together, one larger than the other, and labelled Chang and Eng, in accordance with the relative size of the twins. The passage of this natural vegetable phenomenon at such a time caused considerable merriment.

The useless ban of secrecy being removed by the officially recognized publication of the report in the *Times* of this city, I do not feel that I am committing any indiscretion towards the College in forwarding this communication, in spite of the refusal which I have received.

I am, yours truly,
J. SOLIS COHEN.

PHILADELPHIA, Feb. 19.

A WORD IN REGARD TO THE HISTORY OF THE OPHTHALMOSCOPE AS AN OPTOMETER.*

By EDW. G. LORING, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Through the courtesy of the President of the County Medical Society of New York, I was invited to be present at the meeting of Nov. 24th, and to take part in the discussion which followed the reading of the paper entitled "Ophthalmoscopic Optometry," and which was published later in *THE RECORD*, under date of Jan. 15th, p. 30.

From the emphasis with which Dr. Knapp dwelt upon the fact in his introductory sentences, I was led to believe that the chief claim that he had for the kind indulgence of his audience was the fact of the "novelty" of the subject of his paper, and its great, though comparatively little recognized, importance in ophthalmic practice.

Hearing this, and knowing the reader's great erudition, and his intimate and exact knowledge of everything which pertains as well to the theory as the practical application of the ophthalmoscope, I was surprised to hear him, in his first formal proposition concerning it, say: "A comparatively new field is its use as an optometer; that is, (1)† the determination of the refraction of an eye independently of the statements of the patient" (loc. cit., p. 30).

It does not seem to me that the above accords with the correct statements of the facts of the case. Helmholtz, in 1851, or twenty-three years ago, first published his description of the ophthalmoscope, and "it is interesting to see," as Mauthner observes, "how perfectly the inventor of the ophthalmoscope understood the entire range of its capabilities in determining the refraction of the eye." "By its means," to quote the words of Helmholtz himself, "the observer has the ability to determine the optical condition of the eye independently of the statements of the patient."

Words uttered twenty-three years ago strangely similar to those with which Dr. Knapp now ushers in a comparatively new field in ophthalmoscopy.

In 1856, or eighteen years ago, Ed. Jaeger published a treatise on "The Ophthalmoscope as an Optometer," and in speaking of this work, Donders (*Anom. of Refraction*, p. 331) says: "Von Jaeger, following the example of Helmholtz (Berlin, 1851), early recommended the ophthalmoscope for the determination of the refraction of the eye, and he has undoubtedly acquired great expertness in the use of this method. His

observations extend over more than 1,600 eyes." And this eighteen years ago!

In 1861, or twelve years ago, Jaeger republished his views on the "Ophthalmoscope as an Optometer" (*Ueber die Einstellungen*, etc. Wien, 1861). This second publication was translated into the *Annales d'Oculistique* for July and August, 1862. In the same year Dr. Hay, of Boston, translated it into English, for the *Medical and Surgical Journal* of that city (Dec. 1862). And Stellwag in his first edition (1862) also speaks briefly but clearly of the advantages of this method of determining the refraction.

In 1864, Donders, in his great work, gives, as is his wont, a short but exceedingly lucid explanation of the whole matter, with, however, some objections to the method, which, as Mauthner shows in his own exhaustive treatises on the subject (1867-68) were more imaginary than real. It is to this last author, more than any other, that the ophthalmoscope as an optometer owes its present perfection. And finally, in 1870, the writer of these remarks published a long paper in the *Journal of Medical Sciences*, with a profuseness of illustration adapted for those who, like himself, were wanting in mathematical acquirements.

With such a chronological record as this before him, Dr. Knapp introduced as a "novelty," for the consideration of the County Medical Society, the "use of the ophthalmoscope as an optometer," "a comparatively new field," in which the name of the earliest explorer mentioned is his own, in 1867. And after being reminded, in the detailed discussion which followed, of his illustrious predecessors, the paper is published in one of the standard journals of the day without an allusion to any one of them.

In regard to the second division of the uses of the ophthalmoscope, that is, "the determination of elevations and depressions on the background of the eye," Dr. Knapp himself begins by saying: "The method of ascertaining the relief of the background of the eye is only a repetition of the determination of the state of refraction." The rules and formulae for this were laid down by Helmholtz in 1851. That is to say, given the rules how to make a geometrical measurement, and the standard of measurement, we have simply to make such measurements. "This method," says Dr. Knapp, "of determining the relief of the background of the eye, was first described by myself at the Congrès International d'Ophthalmologie at Paris, in August, 1867, and published in the Transactions of that society, p. 165. A year later Mauthner described it in his exhaustive treatise on the ophthalmoscope, Vienna, 1868." It is true that Mauthner did describe it in 1868; but Dr. Knapp neglects to state that this was not the first time that he described it.

Mauthner's treatise appeared in 1867, not, "a year later, in 1868." The title of this work is the "Determination of the Anomalies of the Refraction by Means of the Ophthalmoscope, Vienna, 1867;" also, Leipzig, Fues's Verlag, 1867.

After having been informed of this fact at the meeting, if the author of the paper had had any doubt as to the correctness of the information, he might have convinced himself by turning to p. 46 (loc. cit.), where he would have found a full discussion of the determination of the relief of the bottom of the eye, and on p. 66 a mathematical exposition of the formula by which the "estimation of different levels" is computed. He would also have found there, given seven years ago, the formula for the calculation of l_1 which he now promises to give in a forthcoming number of his Archives. From the formula which Mauthner took from Helmholtz, $l_1 l_2 = F' F'$ I calculated (1870)

* Ophthalmoscopic Optometry and Demonstration of a new Ophthalmoscope. H. Knapp, M.D.

† The italics are the author's.

the different valuations of l_2 for all the more commonly occurring degrees of refraction from $\frac{1}{4}$ to $\frac{1}{30}$. These tables have been in use for the past four years; but I regret to say that their practical importance is less than I hoped would be the case.

Mauthner's later work, into which this pamphlet was incorporated, "Text-book of Ophthalmology," appeared as a whole in 1868, though the first part of even this later work came out originally in 1867. And this in its turn was but the elaboration of some earlier articles published during the previous year in the *Austrian Journal of Medical Science*.^{*} In number 52 of this journal, for the year 1866, Mauthner, by means of mathematical formulæ and clinical examples, gives a thorough exposition of the method of determining the different levels of the bottom of the eye—a method which Dr. Knapp now claims was first described by himself in 1867; consequently Mauthner's paper was printed eight months before the Congress took place at Paris, and considerably over a year before its Transactions, which contained Dr. Knapp's paper, were published (1868).

It would also appear that there has been a mistake in regard to Dr. Knapp's assertion that his cases of "hyperopia of $\frac{1}{4}$ in one eye and $\frac{1}{3\frac{1}{2}}$ in the other are the highest degrees of that anomaly ever observed in eyes possessed of their crystalline lenses"—a mistake which the most casual examination of the literature would have prevented. Thus Donders, p. 241, observes in the case of Dr. De Haas: "It appears that Hm amounts to very nearly $\frac{1}{4}$, and nevertheless, with strong convergence, Dr. De Haas still attains to nearly the accommodation for parallel rays." On page 258 he mentions a case of H of $\frac{1}{2\frac{1}{2}}$ in one eye and $\frac{1}{3\frac{1}{2}}$ in the other; on page 258, he gives a case reported by Bowman, "in which glasses of $\frac{1}{1\frac{1}{2}}$ being employed for distant vision, the degree of H was = $\frac{1}{1\frac{1}{2}}$," and on page 290 a detailed account of this case is given by Bowman, who says that he "perfectly satisfied himself that the lenses were present." I have myself, through the kindness of Dr. Cutter, of the N. Y. Infirmary, seen a case within the past month where the Hm was $\frac{1}{2\frac{1}{2}}$ as measured both by the ophthalmoscope and by glasses. Mr. Bowman's case is a fac-simile of the case reported by Dr. Knapp, only the H was twice as much as that in the most ametropic eye mentioned by the latter.

I have been induced to make the above remarks, independently of the interest of the subject, out of a sense of justice to the great names which rescued the specialty which I practise from the hands of charlatans, and elevated it to a scientific standing, and who have for the past quarter of a century, whatever may be its present tendencies, maintained its dignity as well by their practice as their teaching.

A NEW APPLICATION FOR ESMARCH'S ELASTIC WEBBING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Esmarch's use of elastic webbing for bandaging the limb in his "bloodless operations," suggests its application in cases of extreme prostration from hemorrhage or other analogous causes, instead of the simple local constriction of the limb heretofore practised. It would not be an exaggerated estimate, perhaps, if we assumed that by bandaging all the extremities in this

way we could effect a temporary addition of twenty-five per cent. to the amount of blood circulating through the vital organs.

Yours, etc.,

ANDREW H. SMITH, M.D.

110 EAST 38TH STREET, Feb. 5th, 1874.

SOME OF THE INFLUENCES OF HYGIENE ON THERAPEUTICS.

By J. R. BLACK, M.D.,

NEWARK, OHIO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Perhaps one who, in an active professional life of a little more than twenty years, its first decade graced by no more than an ordinary professional knowledge of hygiene, part of the last almost embarrassed by an endeavor to grasp and formulate its ultimate and most comprehensive truths,* may be in position to communicate somewhat on the practical relation of the principles of prevention to those of cure. At the least, one who has undergone the experience of seldom thinking, and then of thinking a great deal, upon the relation of sanitary truths to practical therapeutics, must be sensible of the disadvantages of the one, or the advantages of the other, as the case may be. A brief analytical view of this experience, in one or two aspects, is what I now purpose to give.

A truth that steadily grows in the mind as the knowledge of sanitary science increases, is, that the number of diseases which cannot be avoided is exceedingly small. Indeed, an ideal state becomes readily conceivable in which inherited taints and imperfections may be obliterated—in which any one may attain so nearly to absolute purity, and to an absolute perfection of constitution, that disease would be almost unknown; abolishing premature death, except by accident, and rendering natural death by the harmonies and progressive decay of each organ of the body, as in pure old age, the rule, instead of the rare exception.

If there is an undue tendency to regard disease as an entity rather than a condition, no more effectual means of contraction can be adopted than in the study of hygiene. It makes plain to the mind the conditions amid which many diseases are begotten; the phenomena of disorder, without puzzling the mind with endless minutiae of exact changes in form or function, as if, when we have found these, we have the causes, instead of the products, of morbid action.

After all, what can ever be known of the essential or ultimate causes of morbid action—what more than its mere appearances? The verdict of modern philosophy is nothing. As Herbert Spencer states it (I quote from memory), of causes ultimate or otherwise, we can know nothing, only the succession and relation of phenomena; all else is of the unknowable. If it is supposed that in the transformation or accumulation, etc., of a little plastic matter in the pulmonary vesicles the ultimate cause of tuberculosis may be discerned, and this once attained, physicians may then set about its removal by rational rather than empirical means; the old-time mistake of taking appearances for the essence of things will be made. Take a little of the matter from a syphilitic ulcer, examine it carefully with the microscope, the spectroscope, with all the appropriate senses and their aids, and there is nothing which can

* *Oesterreich. Zeitschrift für praktische Heilkunde.* Wien, Dec. 1866, No. 52.

* The Ten Laws of Health.

be discerned that would enable any one to predict *a priori* that it would, when introduced into the blood of a healthy person, produce the series of sensations and appearances which it has the well-known power to do. Nor when able, as in this case, and in hydrophobia, to isolate the *matres morbi*, is there a ray of light thereby gained into the best means of counteracting its disastrous effects on the body.

The study of hygiene makes the doctrine clear to the mind, that a simple variation of an aggregate of circumstances, conditions, and habits, is capable of giving rise to a marked variation in the type of disease, or, as some think, to a new form of disease, as in typho-malarial fever. This was unmistakably seen during the late war, in which the soldiers, from a simple variation of habits and circumstances, suffered by a form of diarrhoea and of fever very different from that which prevailed at their homes, or from that which prevailed among the inhabitants of the regions among which they were encamped. There was then no new entity, only a new aggregate of conditions; and why it acted upon vital force and brought about a peculiar form of morbid action, we will never know any more than we will ever know why aloes purge or strychnine convulses.

A thorough knowledge of hygiene contributes in an eminent degree to successful therapeutics. When advice is required by a person in the incipient stage of consumption, he would not simply receive a prescription for some medicine, with the brief advice to go home and take care of himself. Such advice, in nine cases out of ten, is taken to mean that he must keep in a close, warm house in rough weather; that he must be careful not to take cold by allowing any fresh night-air to reach him in his bedroom, and that he may give his lungs for an hour or two on fine days the benefit of a pure outdoor-air. The fact does not occur to the mind of such an adviser that the natural food of the lungs is pure air; that the mere fact of its expulsion once from the lungs, after an instant's contact, is *prima facie* evidence of its unfitness by contamination, even in that short time, for the purposes of healthy life; and that the lungs cannot be properly fed in an hour or two each day, but that they require wholesome nourishment sixteen times every minute, or more than twenty thousand times a day. In thinking of all this, and of the additional fact that, while consumption is unknown among animals that breathe pure outdoor-air day and night, it soon manifests itself when they are housed and confined in stagnant air, the medical adviser would insist on pure air for the lungs during every minute of the day and night, and, to those able to afford it, to seek the *best quality* of lung-food the continent affords, where every breath exhilarates and makes the blood-corpuscles to tingle in the capillaries with exuberant life.

The practitioner unacquainted with hygiene is very likely to manage a case of dyspepsia thus: he directs some medicament to relieve the most urgent symptoms, with perhaps a tonic for the debilitated organ; the patient is also cautioned to be careful in his diet, with perhaps a prohibition or two. Now, what is the ordinary result of such treatment and directions? Why, the sufferer may be relieved for a few days, but in a week all his miseries have returned. He goes through a like course again and again with the same results, until, utterly disheartened, he tries another and another doctor, seeking rest and ease, and finding none. The hygienist who has gone to the bottom of such troubles, that is, to their origin, in addition to his medicines, advises thus: You must let all forms of pastry and sweetcakes alone; eat no more warm bread unless it

be Graham biseuit;* avoid all fried foods and those of a very fatty nature; eat no concentrated preparations, like a preserve or marmalade; eat slowly; masticate well; do not give your stomach the work your teeth ought to do; do not drink while you eat, washing your food into the stomach in a lumpy condition and without the due admixture of saliva; do not partake of a variety of foods at a time, but make a meal out of the two or three articles you commence with; change your diet as you please, from meal to meal, but absolute simplicity in each is indispensable. Under these directions, faithfully carried out, with a little medicine, I have not met with a case of dyspepsia that did not steadily and progressively recover.

In the past three days two cases of periosteal inflammation and incipient caries—one of the os innominata, the other of the ulna and radius—were brought to me from a distance. Both are the sons of hale, hearty farmers, living in healthy districts. The age of one is eight, the other ten. The disease in each is of some months' standing, and pronounced by more than one of the previous medical attendants to be of a scrofulous character. Yet there was no perceptible glandular enlargements, nor anything of the kind in any of the members of, either family. What, then, is the cause of the disease in such cases? The hygienist would probably give a very different answer from the pathologist. For one, I am convinced that the true explanation of the great frequency of osseous diseases in the young, while the bones are undergoing rapid development, is that the blood is too poor in the elements on which their enlargement depends. The salient facts in such cases are these: that nearly all idiopathic bone-diseases and deformities occur in the young during the period of rapid growth; that the amount of the phosphates which would properly nourish the osseous system of an adult would not do so in a child, and that by the prevailing system of dietetics nearly the whole of the phosphates are eliminated from our standard foods. The shell of phosphates which underlie the husks of the cereals is carefully excluded; the arts and pampered tastes of men are taken as better guides to what constitutes a wholesome and proportionate ratio of elements for the proper nourishment of all the tissues of the body at different periods of life, than the unheeded cravings (morbid though they often are, as in the dirt and limbecating habit) and the wisdom of constructive nature.

Therefore, in the treatment of all forms of osseous diseases in the young, the digestive organs acting normally, it should be a leading object to enrich the blood with all the elements upon which their healthy growth depends. And this should be done by giving to the young sufferer the needful earthy matter in an organic form, or as it is prepared for us by nature from inorganic matter. The products of the laboratory of the chemist are not a substitute for those of nature. No generalization is clearer than this, that though all the elements of our bodies exist in the inorganic world, they are not fit for assimilation until raised and knit together by the force of vegetative life. A syrup of the phosphates is therefore not a substitute for the shell of phosphates which lie underneath, and is commonly separated and thrown away with the outer

* The reason why ordinary warm bread is hurtful arises from a simple mechanical condition. Mastication reduces it to a doughy state, so that the gastric juice cannot penetrate its mass, but can only act upon its outside, and before the inside is reached fermentation has occurred. But suppose that in place of refined, unbolled flour is used, as in Graham biseuit; the coarseness of the bread-texture enables the gastric juice to penetrate and digest its mass at once, and no inconvenience is felt even by the confirmed dyspeptic. Let those who do not believe, put it to the test.

covering of the wheat kernel. Chemically pure carbon, in any of its allotropic forms, will not make fat; no more can bone, or skin, or hair be made or nourished out of any inorganic concoction of their elements.

Medical Items and News.

THE SIAMESE TWINS.—A partial post-mortem examination of the band which joins these twins has been made, under the direction of the College of Physicians of Philadelphia, by Professors Wm. H. Pancoast and Harrison Allen. From an official report of the same, made on Wednesday evening, Feb. 18th, and published in the *Philadelphia Medical Times*, we make the following abstract:

The band was four inches long and eight inches in circumference, and was made up of a fibro-cartilaginous union of the ensiform cartilages, the fasciæ of the oblique, the rectus, and transversalis muscles, and contained three peritoneal pouches, two from Chang (the left twin) and one from Eng (the right twin), crossing each other at the median line, Eng's pouch dovetailing the other two. The upper pouch of Chang, which was the largest of the three, was, like the others, empty; but was supposed by Prof. Allen to have contained, in the fetal condition, liver-tissue. This he denominated the hepatic pouch. Besides these, there was direct communication of the two livers with each other, through a solid isthmus, as was made evident by the fact that plaster, colored by ultramarine, was thrown into a tributary of the portal vein of Chang, when it was observed that the fluid passed freely into the liver of Eng.

The hypogastric arteries ran upward in each body into the band, and were lost toward the common umbilicus in the anterior-inferior surface of the middle of the band. The band itself was covered with integument fascia. The opinion of Prof. Allen, as to the

cause of death of Chang, was cerebral clot, while Eng died of fright, one evidence of which was an enormously distended bladder.

Dr. A. Jacobi, of this city, who was present at the meeting, remarked as follows:

As far as the origin of twin monsters is concerned, I am certainly of those who are not of the opinion that two individuals could get into such an intimate connection by growing together. Certainly the connection is a more intimate and original one. I believe that the general opinion is now that one Graafian body may contain two ova, or one ovum have two nuclei. During fetal life, the first development of the ovaries takes place from a conglomeration of cells. Part of these form into germinal cells, part into connective tissue. The former are, or are developing into, the ovum that will be, with its nucleus, plasma, and membrane. The latter is formed in lesser or greater quantities. When its layers are but thin between two germinal cells, two ova may get enveloped in one Graafian body, or even two nuclei in one ovum. Thus one menstruation may yield two ova, or an ovum with two germinal centres. I think this will also explain why the sex is always the same—why they are always both male or both female. They are male in but twenty or twenty-five per cent. of the cases.

The peculiar conditions under which the autopsical examination was carried on, rendered it impossible to settle these, among other points, and the dissection of the band not being complete, a more detailed report is promised.

The following interesting account of the physical condition of the twins is likewise extracted from the *Philadelphia Medical Times*, and furnished by Dr. Hollingsworth, for twenty years the attending physician of the twins at Mount Airy, N. C.:

"Their habits were very active. During the latter part of their life they and their families lived in two houses, about a mile and a half apart, and it was an inflexible rule that they should pass three days alternately at each house. So determinedly was this alternation maintained, that sickness and death in one family had no effect upon the movements of the father, and a dying or dead child was, on one occasion, left in obedience to it; indeed, Dr. Hollingsworth is very positively of the opinion that the death of the twins themselves was the result of this rule, or, at least, was materially hastened thereby.

"The evidences during life that the twins were physiologically distinct entities were very numerous and apparent. They were different in form, tastes, and disposition; all their physical functions were performed separately and unconnectedly. What Chang liked to eat, Eng detested. Eng was very good-natured, Chang cross and irritable. The sickness of one had no effect upon the other, so that while one would be suffering from fever, the pulse of the other would beat at its natural rate. The twins not rarely suffered from bilious attacks, but one never suffered at the same time as the other; a circumstance which seems somewhat singular in view of the close connection which the post-mortem has shown to exist between the livers of the pair. Chang drank pretty heavily—at times getting drunk; but Eng never felt any influence from the debauch of his brother—a seemingly conclusive proof that there was no free interchange in their circulations.

"The twins often quarrelled; and, of course, under the circumstances, their quarrels were bitter. They sometimes came to blows, and on one occasion came under the jurisdiction of the courts. After one of these difficulties Chang and Eng applied to Dr. Hollingsworth to separate them, stating that they could

not live longer together. Eng affirmed that Chang was so bad that he could live no longer with him; and Chang stated that he was satisfied to be separated, only asking that he be given an equal chance with his brother, and that the band be cut exactly in the middle. But as Dr. Hollingsworth advised very decidedly against this, and declined to interfere, cooler councils prevailed.

"In August, 1870, Chang suffered from a paralytic stroke, from which he never fully recovered; and during the last year of his life he several times said to Dr. Hollingsworth, 'We can't live long.'

"On the Thursday evening preceding their death, the time having arrived for their departure from the house at which they were staying, the twins rode a mile and a half in an open wagon. The weather was very cold—the night being the severest of the winter. Chang had been complaining for some days of cough, with distress and actual pain in the chest. He was so unwell that his wife thought he would be unable to bear the trip; but he finally went. On Friday morning Chang reported that he felt better, but that in the night he had had such pain in the chest, and so much distress, that he thought he should have died.

"The twins slept in a room by themselves, or with only a very young child present; and some time in the course of Friday night they got up and sat by the fire. As they were accustomed to do this frequently, nothing was thought of it by those of the family who saw them, even though they heard Eng say he was sleepy, and wanted to retire, and Chang insisting on remaining up, stating that his breathing was so bad that it would kill him to lie down. Finally, however, the couple went to bed again, and after an hour or so the family heard some one call. No one went to the twins for some little time, and when they did go, Chang was dead and Eng was awake. He told his wife that he was very 'bad off,' and could not live. He complained of agonizing pain and distress, especially in his limbs. His surface was covered with a cold sweat. At his request his wife and children rubbed his legs and arms, and pulled and stretched them forcibly. This was steadily continued until he went into a stupor, which took place about an hour after the family were alarmed. The stupor continued up to death; according to the statements of the family, there were no convulsions."

Braithwaite's Retrospect ceased its existence with the January number. Its further publication has been considered unnecessary in view of the general adoption, by medical journals, of a department devoted to the progress of medical science.

ARMY STAFF RANK.—At a meeting of the New York Academy of Medicine, held January, 1874, the following resolutions were adopted:

Resolved, That the members of the New York Academy of Medicine do hereby cordially unite with those of the American Medical Association in its memorial to Congress in support of a bill to increase the Efficiency of the Medical Department of the Army of the United States, now before that honorable body.

They consider it an act of justice that the members of so important a branch of the service, gentlemen of the highest professional attainments and excellence of character, and charged with such highly responsible duties, should hold the same relative rank and enjoy the same emoluments as members of the other staff corps of the army.

That it be respectfully urged, upon the members of Congress from the City and County of New York, to use their influence in support of the bill in question.

That a copy of the above resolutions, duly authenticated, together with a copy of the memorial pamphlet, be furnished to each member of Congress.

Resolved, Also, that a copy of these proceedings be furnished for publication to the medical journals.

JOHN C. PETERS, M.D.

GURDON BUCK, M.D.

FRANK H. HAMILTON, M.D.

} *Committee.*

The undersigned, a committee appointed by the Medical Society of the County of New York, highly approve of the action of the American Medical Association and of the New York Academy of Medicine in favor of a bill now before Congress to increase the efficiency of the Medical Department of the Army of the United States, and warmly recommend the adoption of the same by the Medical Society of the County of New York.

A. C. POST, M.D.

J. E. TAYLOR, M.D.

} *Committee.*

THE REGULATION OF INSANE ASYLUMS.—A bill has been introduced into the New York Legislature on this subject, providing as follows:

"The Governor of the State is authorized to appoint for the City and County of New York not less than ten nor more than fifty, and in every other county not less than five nor more than twenty, reputable physicians, to be known as Examiners of Lunacy, and to fill vacancies occurring among such examiners as they occur; and in every case arising in any county requiring, as now provided by law, the certificate of two physicians to authorize the confinement for safe keeping of any person on the ground of lunacy, such certificate shall be required to be signed by two of the Examiners of Lunacy so appointed, resident in the county in which such case of lunacy is found; and no person shall be received as a lunatic in any asylum, public or private, without such certificate."

Up to the time of our going to press its fate is undecided. If the said bill should pass, and the proper persons be appointed on the commission, it may serve a good purpose. It is unnecessary to assume that such gentlemen should be well-educated alienists. This being the case, we shall then have the initiative taken towards establishing a corps of experts on insanity, whose duty it may be to examine all cases of doubtful insanity that may come before the courts.

JOSEPH MATHER SMITH ANNUAL PRIZE.—This Fund is endowed by the relatives of the late Dr. Smith, in memorial of his services as Professor in the College of Physicians and Surgeons from 1826 to 1866. Under its provisions an Annual Prize of One Hundred Dollars will be awarded for the best essay on the subject for the year, presented by an alumnus of this College, or a member of the graduating class. The Prize Committee, consisting of the President of the College, the Professor of Pathology and Practical Medicine, and the President of the Alumni Association, shall designate each year the subject for the following year. The competing essays should be sent to the President of the College on or before the 1st of February in each year; each essay to be signed with a device or motto, and accompanied by a sealed envelope inscribed with the same device or motto, and containing the name of the author. The envelope of the successful essay to be opened, and the prize awarded, at the Annual Commencement.

The subject of the prize to be awarded in March, 1875, is Hygiene, in either of its Special Departments.

Original Lectures.

A LECTURE ON THE
MEANS EMPLOYED FOR THE RELIEF OF
STRANGULATED HERNIA,ESPECIALLY THE OPERATION OF NOT OPENING THE
SAC.

DELIVERED AT THE UNIVERSITY MEDICAL COLLEGE.*

By ERSKINE MASON, M.D.,

ADJUNCT PROFESSOR OF SURGERY.

HAVING described the means employed for the purpose of effecting the reduction of a hernia, we shall, this afternoon, gentlemen, consider a little more fully some of the features of these operations, but more especially in reference to that one of not opening the sac. I shall preface these remarks by saying, that, perhaps, in the whole range of operative surgery, there is none of more interest to the surgeon, and upon the result of which depends so much the future welfare of the patient, as that which we resort to for the relief of a strangulated hernia. It, therefore, is essential for you all to thoroughly study this subject, no matter whether you intend to practise surgery or only desire to confine yourselves to the mere practice of medicine. So often, and that without the slightest premonitory symptom, may strangulated hernia occur, and so prompt in many instances should relief be afforded, that all who practise the healing art may be called to administer to a patient contending with this affection, and at a time and when circumstances do not permit of a surgeon seeing the case. Hence you should all be prepared, should occasion demand it, to afford that relief to your patient which the knife often affords.

Some years ago, surgeons, when called upon to relieve a strangulated hernia, taxis having failed, would, after having divided the different layers of tissue surrounding the sac, proceed to lay open the sac and divide the stricture, and then, if the contents of the sac were found in a suitable condition, return them to the cavity of the abdomen; and even at the present time this is the more common custom. That the operation may be freed of many of the dangers attendant thereon, and the results prove more satisfactory by pursuing a different course, and one that is admissible in very many cases, I shall endeavor in this lecture to show you. I believe that the operation, without laying open the sac, is one that may often be performed with facility, and is applicable to many small as well as large hernie, and should be more frequently practised than is the case.

Let us consider, first, what are the means which we may resort to in reducing a strangulated hernia, what are the dangers attending them, and how may these dangers be decreased, or in a great measure avoided? When called to see a patient suffering from a strangulated hernia, our first endeavor should be to restore the parts to their normal position, without having recourse to the knife, unless certain symptoms are present, which I have previously alluded to; and this is done by what is known as taxis, with or without the many adjuvants we may call to our assistance. In order that the taxis shall be of any avail, it should be applied in a scientific manner, and to do this requires, on the part of the operator, a thorough understanding

of the anatomy of the structures involved in this disease, as well as the variety and kind of hernia which he has to deal with. The greatest care and delicacy of manipulation is requisite in the performance of this apparently, to some, simple matter. A cardinal rule in the use of this means is to induce that portion which has come down last to return first. That we are to derive great advantage from adjuvants in this proceeding, none who have had any experience in the treatment of this affection will deny. Position alone will often accomplish our object, without any resort to manipulations, and in some cases even after the taxis has proved ineffectual, the simple elevation of the foot of the bed has been known to cause the hernia to return. The warm bath, bleeding, the use of ice to the part, all hold an important place among what we call the adjuvants to taxis. But first among all stands anæsthetics. Well for the patient, and for the success of surgery, the use of emetics and tobacco clysters, and all that tends to prostrate the strength, have been banished from our list. But has taxis no dangers attendant upon it? is it never productive of harm? On the contrary, many a poor patient has had his doom sealed by this method, and the fatal result has been laid at the door of the cutting operation. The use of taxis, I feel confident, has done much to increase the mortality of this disease, and cause the results of the knife to assume so sad a place among the capital operations in surgery. I refer now to rough handling of the parts and the long-continued use of taxis in unskilful hands. The valuable time that is lost in these oft-repeated operations, and the injury the parts have received through such means, no surgeon will cease to regret or condemn. It cannot be doubted that in many cases the parts have been so contused and injured, that, no matter what operation is then resorted to, or how soon after such mischief has occurred, the chances of saving life, if not altogether destroyed, are greatly diminished. That accident of reduction *en masse*, which we spoke of the other day, is the result of an ignorant use of the taxis. If, then, the too frequent resource and prolonged attempt at taxis, even at the hands of one thoroughly competent to use it, may be productive of harm, the question arises, When shall we relinquish the taxis and resort to the knife? That this may often be a very nice question to decide, and one which the oldest head and most experienced hand may at times be in doubt about, I will freely admit. Before committing ourselves to any line of conduct, let me give you the opinions of some of those who have given attention to this subject, and recorded their ideas for the benefit of their professional brethren. Mr. Key, in speaking upon this subject, expresses himself thus: "I can scarcely press in too strong terms the necessity of an early recourse to the operation, as the most effectual method of preserving life in this dangerous disease." Mr. Pott thought that the operation, when performed in a proper manner and in due time, did not prove the cause of death oftener than once in fifty times; and he states that he has often had occasion to lament he had operated too late, but never of having resorted to the operation too soon; and closes his remarks with this sentence: "The delay of a few hours may cut off all hope of success, when a speedy operation might have saved the life of the patient." Sir A. Cooper believed that pain on pressure of the abdomen, and tension, were the signs that point to its immediate necessity. "Indeed," says he, "there is scarcely any period of the symptoms which should forbid the operation; for even if mortification has actually begun, the operation may be the means of saving life, by promoting the ready separation of gangrenous parts." Though the practice of

* January 30, 1874.

the older surgeons may have delayed the operation too long a time, owing to their regarding the knife in so serious a light, and as the last and almost hopeless resort, the verdict of modern surgery is almost unanimous in recommending a much earlier resort to the knife. That this is a correct view of the subject the record of cases at the London Hospital readily shows. The ratio of mortality increases greatly in proportion to the length of time that the strangulation is allowed to continue. Of 69 cases of strangulated hernia reported by Mr. Luke occurring in the above institution, and operated upon in the first 48 hours, 12 died, or 1 in 5.7; while of 38 cases operated on after more than 48 hours had elapsed, 15 died, or 1 in 2.5.

Cutting operations for the relief of the strangulation are two in number, known as the division of the stricture from within the sac, and that of division outside or external to the sac. The first of these is the old operation, and the one which thus far has had the most advocates, and is more frequently performed to-day in all cases than any other. Indeed, the merits or demerits of the other often appear to be unknown to many of the profession. That the operation of opening the sac is surrounded by many dangers, and is often entirely unjustifiable, I firmly believe. Now, what are the dangers and advantages which are attendant upon opening the sac? First, as to the dangers:

1. The great risk of wounding the gut, which is very great in the hands of inexperienced operators, and even those who are the most dexterous with the knife have met with this accident; for the viscera may be adherent to the sac at the place of incision, and thus be wounded; and this condition of the parts in very many cases cannot be determined beforehand.

2. After the sac is opened the gut may be injured by rising over the edge of the knife while we are in the act of dividing the stricture.

3. Some of the constituents of the spermatic cord, especially when they pass over the tumor, have been wounded, especially the vas deferens.

4. If the hernia is very large and irreducible, the contents are liable to inflame and cause fatal peritonitis.

5. In case of wounding any large artery, as the epigastric or obturator, the blood is liable to flow into the cavity of the abdomen, and by its presence give rise to fatal peritonitis.

6. The wound of the peritoneum may give rise to general peritonitis, even though this membrane is not already in an inflamed state.

7. The exposure to the atmospheric air of a congested or inflamed intestine, and the dangers which arise from the direct handling of the same.

This is a great cause of danger, and however strong the rules may be laid down against rough or unnecessary handling of the viscera, the tendency of some operators to finger the parts during all operations appears so irresistible, that all rules seem of no avail to shield the parts from dangerous meddling.

So much for some of the dangers attendant upon this mode of operation. Let us look at some statistics of the operation. Mr. Luke, in reference to this method, says, that out of 84 cases he opened the sac in 25, while in 59 the sac remained unopened. Of the 25 thus operated on, 8 died, whereas in the 59 upon whom the other method was used, only 7 died; and of 545 cases collected by Dr. Turner, and reported in Mr. Erichsen's work on surgery, 260 are said to have died.

The advantages claimed for this operation are as follows:

1. By laying open the sac we see the condition of the strangulated parts, and thus, if the gut be torn or in a gangrenous state, we are prevented from returning it.

2. That we are in no danger of reducing the parts still in a state of constriction, either by bands in the sac, or by the omentum being folded so tightly around the intestine as to be a source of strangulation.

3. That we can thus apply means for the restoration of congested portions of viscera.

These, I believe, embrace the advantages which are awarded to this operation; and without pursuing this method the operation for strangulated hernia would not be regarded by some as having been properly done.

With this reference to the old and most frequent operation, let us turn to the consideration of that which is more modern, viz., the operation "without opening the sac."

Franco and Paré were the first to cut without opening the sac, according to Mr. South in his notes to Chelius's System of Surgery, though to Jean Louis Petit belongs the honor of first recommending this operation. He described the operation, gave his reasons for adopting it, and answered objections raised against it. He performed the operation first in 1718, and advised it in not only old and large hernie adherent to the sac, but also recommended its more general practice. Ravaton, in 1750, in his work on gunshot wounds, introduces it as a new operation, and mentions having performed the same successfully in three instances. The operation was also recommended in large and old ruptures by Sir A. Cooper. Though with such strong advocates, the operation appears not to have met with general favor. The revival of this operation was due to Mr. Key, who, in a clinical lecture delivered in 1829, drew attention towards it, and in 1833 gave to the profession his memoir on the "Advantages and Practicability of Dividing the Stricture in Strangulated Hernia on the Outside of the Sac."

In this work he strongly advises it as a general mode of operating. Mr. Luke also strongly advocated this method, and the results of his operation I have given you.

Mr. Erichsen, in his work on surgery, says: "I am decidedly of the opinion that this operation should always be attempted in preference to the ordinary one of opening the sac, in those cases in which the hernia has not long been strangulated, and presents no sign of the occurrence of gangrene in it, and more especially when it is femoral." In this country I am of the opinion that this operation is not the one that is generally resorted to.

The advantages claimed for this operation are:

1. The great simplicity warmly commends it.

2. The peritoneal cavity is not opened.

3. The peritoneum at the mouth of the sac is not wounded.

4. The diseased viscera are not exposed to the influence of the atmospheric air.

5. The fingers of the surgeon, or assistants, are prevented from directly handling the intestines or omentum.

6. In case there should be considerable hemorrhage, there is no danger of the blood entering the cavity of the peritoneum.

7. The danger of wounding the intestine is avoided.

Objections to the operation:

These are, in the opinion of some, that, 1. When there is a necessity for a cutting operation, the sac should be opened and its contents examined.

2. That the risk is very great of reducing the hernia, either strangulated by bands, adhesions, omentum, or by even the orifice of the sac itself.

3. The intestine or viscera may be in a state not to warrant its return to the abdominal cavity.

4. The difficulty of the operation itself.

In contrasting the merits and disadvantages of these two operations, in order to determine which should be the method employed in the great majority of cases, we are met with many difficulties, especially when we consult statistics. That the great difficulty lies in finding parallel cases, and that the period of strangulation at which the operations were done carry great weight with them, we are well aware; nevertheless, in this class of operations, as well as in others, we must refer to statistics to assist us in arriving at the advantages one operation possesses over the other.

Statistics of the two operations:

Where the sac was opened. Mr. Textor states that of 56 cases operated upon at Wurtzburg, between 1816 and 1842, 24 died, nearly one-half. Malgaigne states that of 220 cases subjected to operation in the Parisian hospitals, between 1836 and 1840, 133 died, or considerable more than one-half. Of 15 cases published by Mr. South, 6 died. Mr. Luke says of cases published in the British journals, "I some time since ascertained that one-half died." Of 65 cases operated on at the London Hospital, 22 died, or rather more than one-third of the whole number. Mr. Gay states that of 774 cases he has collected, 334 died. Dr. Frank H. Hamilton, in the Bellevue and Charity Hospital Reports for 1870, relates 31 operations for strangulated, inguinal, and femoral hernia; of these 15 died and 16 recovered; with one or two exceptions the strictures were divided within the sac.

That the mortality after this operation is often frightful, you see at once, and whatever mode of operation would hold out greater inducements of success should be welcomed as a great desideratum.

Statistics of the operation without opening the sac:

The greatest number of cases reported of this operation are those by Mr. Luke, who says, "I have attempted the performance of Petit's operation in 84 cases. Of this number the operation was completely successful, without opening the sac, in 59. In 25 it was necessary to open the sac to effect a reduction of the hernial contents, the opening in the sac generally varying in extent from one-half to one-quarter of an inch. With respect to the mortality among these patients: of the 59 in whom the sac remained unopened, 7 died; of the 25 in whom the sac was opened, 8 died. These cases included those of femoral, umbilical, and inguinal. In three of these cases he states that Petit's operation was successfully completed; but the sac was opened, after the reduction of the strangulated parts into the abdomen, to remove some doubts as to their perfect liberation. The proceeding in each case, however, was ascertained to be wholly unnecessary." The result of this operation, therefore, is most favorable when contrasted with those of the former method. Mr. Luke also states that this operation he believes to be more favorable in femoral than in inguinal. Thus, of 31 cases of femoral hernia it was successful in 24, being more than three-fourths of the whole number.

Now with regard to reduction by manipulation. *Taxis*.—That this is not without danger we have referred to in the beginning of this lecture, and Desault, in speaking of this, remarks with much truth: "Always think favorably of a case of strangulated hernia when the taxis has not been used." As we have given some statistics of the other operations, we deem it but right to refer to cases where the hernia has been reduced by this means alone. The following statistics are all we have been able to gather upon this subject: Mr. King states that of 40 patients relieved by taxis, 4 died; Textor, that of 114 patients relieved by this method,

9 died. Of 293 cases occurring in the London hospitals, between 1842 and 1847, 206 were relieved by taxis, among whom no deaths are recorded.

What, then, is the cause of the mortality being so great in this disease? The principal cause is peritonitis; and that the time which has elapsed from the commencement of the trouble to that of the operation, has a great bearing upon the favorable termination of the case, is also evident. The longer the delay the greater the mortality will ever be the rule; that death occurs not only from peritonitis and gangrene of the parts, but from extreme prostration, the result of excessive vomiting, or the effect produced upon the nervous system by a portion of the intestine being constricted, and that without apparent lesion taking place, you should also bear in mind; and I have no doubt but that the mortality following the use of the knife is often due to the exposure and handling of the intestine. It also seems reasonable to think that the wounding of the irritated if not inflamed peritoneum, and the admission of atmospheric air into the peritoneal cavity, may also tend to expedite a fatal issue.

The great objection with which we are met by the advocates of always opening the sac, is the danger of reducing the parts in an unfit condition. That the time a part has been constricted will not always be a sure indication of its condition, is very true; for we see cases where, though the bowel has been strangulated but a few hours, it is found to be in a gangrenous state. Yet, on the other hand, cases are met with which have been suffering from strangulation for days, in which the intestine assumes the normal state after the stricture is relieved. In a majority of cases the condition of the tumor, we should judge, could be ascertained by the condition of the tissues divided in the operation, as well as the appearance of the sac, and the view we obtain of the contents through the same. Should you find the parts doughy, and the elasticity of the tumor to be absent, the sac to have lost its wonted glistening appearance and present a darkened look, and should a fecal or gangrenous odor be added to this, you should expect to find the bowel lacerated or in a mortified state, especially if after the stricture be divided, and the usual remedies for the restoration of the vitality of the parts (such as sponges wet with hot water applied to the sac) should fail. That such restoratives will succeed in restoring the intestine to its natural color, when applied to the sac, after the stricture has been divided, we have verified in our own practice. Let us suppose, now, that we open the sac and find the intestine livid, or of a dark chocolate hue, with spots of ecchymosis upon its surface; it will be difficult for you to decide, at times, whether or not the intestine should be returned to the abdominal cavity. I recall to mind a case where several surgeons of great eminence were at a loss to decide upon the proper course to be pursued in just such a case, some inclining to the opinion that to return the part would be fraught with danger. The intestine was returned, however, and the woman recovered. This case only goes to show that surgeons of equal experience, and regarded by the profession as exercising sound judgment, would often be led to adopt different measures in similar cases. And if the parts are finally restored to their natural position in such cases, the opening the sac appears to us only to have entailed an additional danger. We strongly believe that the cavity of the abdomen is the safest place, and the one holding greater inducements to recovery, for a portion of bowel greatly discolored, ecchymosed, and almost gangrenous. The opening of the sac is said also to assist nature to form an artificial anus, should rupture of the bowel

take place; that the not opening the sac will not prevent this, has been proved by published cases, and I have seen it verified in my own practice. All resort to the taxis first, yet we know that death has occurred after reduction in this manner, and the bowel has been found discolored and softened; still, little or no objection is made to taxis being tried first in a case of strangulated hernia! Of the 293 cases reported by Mr. Luke, as having been reduced by taxis, none died. Surely some of these cases, if not all, at that time, it may be presumed, were in a condition that, if operated upon, it would have been deemed necessary to have opened the sac and examined the contents, and some perhaps looked upon as being unfit to be returned to the abdominal cavity. Now, would we have had no deaths among those 293 cases of strangulated hernia had the sac been opened? The dangers of reducing the gut, still strangulated, by leaving the sac unopened, we do not believe to be very great; indeed, all the cases that have been reported thus reduced, we think, with but few exceptions, have occurred from the use of taxis alone. Again, when the constriction is produced by bands within the sac, or from folds of omentum, the sac, we should judge, except in *very rare* instances, *must be opened* before reduction can take place; in such cases, therefore, when we have exposed the sac, I do not see how the accident referred to above would very likely happen.

Some of the opponents to the not opening the sac have advanced, as an argument against it, the difficulty of the operation itself, especially in the hands of those inexperienced. I do not think that this operation will often be found a difficult one, though we are fully aware that attempts have been made to do the operation by skilful hands, and the sac has been accidentally opened. Yet, rather than being an unsafe method for those who are not used to the knife, we believe it the safest operation for them to practise. To those who operate for the first time, it is well to bear in mind the rule laid down by Mr. Key in speaking of the femoral variety. He says: "The point of the director should be applied rather to the inner than to the outer part of the neck of the sac, as it will be found more easily to pass under the stricture at this part. It should not at first be attempted to be thrust under the stricture, as the firmness of the parts forming the stricture would resist it. But the seat of the stricture being felt, the operator should depress the end of the director upon the sac, which will yield before it, and then, by an onward movement, the director slides under the stricture."

I think I have shown you that the operation without opening the sac, as a rule, is surrounded with *far less* danger to life than where the sac has been laid open. Though strongly advocating the operation of Petit, I do not wish you to understand that I urge the adoption of it in every case and at all hazards. Perhaps it will be found applicable more frequently to femoral herniæ than to inguinal. In umbilical or ventral it seems appropriate.

There are but few cases in the whole range of herniæ which call for the use of the knife, that will not, we believe, admit of the trial of this method, which entails few if *any* more dangers to a healthy subject than the employment of taxis. Should this fail, we have done nothing to place the life of our patient in jeopardy, and we may then resort to the opening of the sac.

In the division of the sac I would advocate as small an opening as possible, both in dividing the stricture and in examining the contents, and, above all, an abstaining from manipulating both the sac and viscera as much as possible.

The advocating of Petit's operation naturally engenders a belief in the propriety of early resorting to the cutting operation in cases of strangulated hernia. That many valuable lives are sacrificed by delaying an operation, and precious time lost in resorting too long to the use of such adjuvants as opium, injections, cold applications, and hot baths, and even in taxis itself, we firmly believe. Especially to the unwary the use of opium is attended with danger. This is too apt to deaden pain and deceive both the patient and physician as to the true condition of the hernia, and thus give time for the disease to accomplish irreparable mischief. The use of the warm bath, injections, position, and ice applied to the parts, with the taxis, will often succeed in relieving our patient; but we may lose our only chance of safety by delaying too long with these measures.

The safest practice you can adopt, when called to a case of strangulated hernia, is to place the patient thoroughly under the influence of ether, and after a careful attempt in the use of the taxis—the body being elevated, and all that position can do being called to our aid—then, if we fail at reduction, proceed at once to the operation without opening the sac—if not contraindicated—and if division of the sac becomes necessary, make *as small* an opening as the case will admit.

Original Communications.

CASE OF MASTOID INFLAMMATION— PERFORATION OF MASTOID PROCESS —RECOVERY.

By H. G. NEWTON, M.D.,

BROOKLYN, N. Y.

Mrs. D., æt. 32. I was called to see the patient January 17, 1873. She had suffered for five weeks from inflammation of the mastoid cells of the right side. She had been treated by leeches and anodynes. The pain was referred to the occiput and vertex, the patient walking the room pressing her head with both hands. She was dizzy at times, but showed no other signs of cerebral affection. She had an anxious countenance, and was very nervous, due probably to lack of nourishment and sleep, and to the great pain continued through five weeks. Tongue heavily coated, no appetite, and a tendency to constipation. Upon the removal of pus from the meatus, a granulating mass was revealed, projecting from the lower posterior wall at a point one quarter of an inch exterior to the drum membrane. The membrane itself was not perforated. Air passed freely by catheter into the tympanum, with no moist rûle. When the granulations were touched with a probe, intense pain radiated over that side of the head. The region of the mastoid was not painful under pressure—slightly so upon percussion. Patient heard a distinct whisper at five feet.

Ordered two leeches, frequent douching with hot poppy-head infusion, liq. opii comp. at night, and the following: R. Quiniæ sulph., gr. xv.; sodæ bicarb. pulv. rhei, ʒʒ ði.; pulv. ipec., gr. iv. M. et div. in chrt. No. xv. S. One powder three times a day. Granulations touched with sol. nitr. argt. (gr. 120 to ʒi.).

The patient improved under treatment, tongue became nearly clean, appetite increased, and yet more or less pain continued through the month following; the granulations disappeared, leaving a red, shining,

nipple-shaped prominence, from the apex of which oozed very slowly a creamy-looking pus.

Upon the Valsalvian experiment the pus could be forced out a little faster, and at times this also occurred when the catheter was used. The discharge was at no time abundant, but when greatest the patient felt comparatively well; if at any time it ceased, the severe pain returned. Hearing distance remained the same as at first. There continued to be no tenderness upon pressure over the mastoid.

On the 17th of February I found the patient suffering greatly, and there was slight tenderness of the mastoid one inch from the tip. On the 19th, the symptoms remaining the same, it was decided, with the concurrence of Dr. Roosa, to perforate the mastoid process, and this was done with the kind assistance of Dr. R. and my colleagues of the Brooklyn Eye and Ear Hospital. An incision one inch in length was made, commencing at the tip of the mastoid and carried upward, and the periosteum freely divided. No roughened bone was found. A perforation one and a half lines in diameter was carefully made in the median line of the process, half an inch from the tip, the drill being directed slightly upward and forward. When cancellated structure was reached, a bent probe was carefully introduced in the direction of the fistulous opening in the meatus, hoping not only to reach pus, but also to carry a seton through to the opening. In both respects we failed, and were obliged to content ourselves with introducing a tent into the perforation and the external cut.

The tent was removed from the bone on the second day, and not reintroduced. The incision was torn or cut open daily until the first of April, when the patient was so much better that I thought it safe to allow the incision to close. Her condition had been varying, but gradually improving during this period. The hearing distance gradually increased, so that she could hear a distinct whisper at twenty-five feet. The hearing distance has remained the same up to the present time (Jan. 1), and the patient has been entirely well for months.

Remarks.—The foregoing case presents two or three features worthy of attention: First, the membrana tympani was intact; second, there was scarcely any tenderness upon pressure or percussion over the mastoid region, and no periosteal disease, or disease of superficial parts of bone, was found; and thirdly, there was no escape of pus, though the cancellated structure was well opened. These features are not peculiar to this case, but I think they are worth noting.

In many of the cases reported there has been no question as to either the propriety of operating, or the place at which the perforation should be made, for in many of them pus had already accumulated beneath the integuments, and a fistulous opening or a honey-combed condition of the bone was found upon making Wilde's incision.

In the foregoing case there was no doubt concerning the involvement of a portion of the mastoid cells, and the intense suffering of the patient and the continuance of the disease seemed to indicate operative interference. Yet I do not attribute recovery to the perforation of the mastoid (although that may have been a factor in the healing), but chiefly to counter-irritation caused by a free incision opened daily for six weeks. In another such case, however, I should not hesitate to operate, but would make my perforation at the point directed by Dr. A. H. Buck in his excellent article on "Diseases of Mastoid Process" (*vide Archives of Ophthalmology and Otolaryngology*, vol. iii., No. 1), namely, behind the external auditory canal, at a point one quarter of an inch distant from it, and a little below the level of its upper

wall. "The drill should be rotated in a direction inwards, forwards, and a little upwards; that is, nearly parallel with the canal."

Schwartz and Eysell (*Arch. für Ohrenheilkunde*, second vol. of new series) prefer to make the opening with a bone-gouge at a point a little higher than that indicated above, as the mastoid antrum lies somewhat higher than the external meatus, and in order to reach it the chisel must be placed upon the bone below the *linea temporalis*, and inclined at an angle of about 45° to the horizon, and worked inward, downward, and forward. Tröltzsch (the last Am. edition, by Roosa) says: "The instrument is placed on the bone, on a level with the upper border of the outer meatus, from one-fourth to one-half an inch behind the attachment of the auricle, and is worked slightly forward in a horizontal direction."

In the case reported I was deterred from perforating at one of these points by an examination of several temporal bones that were within my reach; for out of these, seven in number, there were two in which it would have been utterly impossible to have perforated at the points mentioned without penetrating the fossa containing the lateral sinus, the fossa being so deeply excavated that only a thin partition of bone was between it and the external surface. In one, indeed, where there was apparently a fine development of the mastoid process, and no external indication of the great depth of the fossa, the bone was translucent.* This accords with the fact that occasionally in operating the fossa is reached rather than the mastoid antrum, an occurrence neither to be foreseen nor avoided.

In the cases for which this operation is, at the present day, undertaken, now and then one might recover under the most active counter-irritation, but the danger to life is so imminent that delay should not be thought of. The surgeon should, however, bear in mind the possibility, just suggested. Fortunately, if the operation is carefully conducted, exposure of the dura mater does not seem to be a very dangerous accident.

In many cases of mastoid inflammation there is a condensation, or even eburnation, of the osseous tissue. In similar circumstances, where there is no great solidifying of the cancellae, I conceive that an abscess in the mastoid may be entirely separated from portions of the cancellated structure by throwing up a wall of neoplastic tissue between it and them, or by filling the cancellae nearest the abscess with dried pus; and that, consequently, we may reach that structure in operating without meeting any pus.

CASES IN WHICH FULLERS' EARTH ACTED AS A SUCCESSFUL SURGICAL DRESSING.

By FREDERICK WILLIAM GODON, A.B., M.D.,

LATE INTERNE ROTUNDO LYING-IN HOSPITAL, DUBLIN, IRELAND.

I BEG leave to present the following cases as the result of the earth-treatment, not that I intend to enter into any discussion upon this mode of surgical dressing, as has already been fully and elaborately done by my friend Dr. A. Hewson, of Philadelphia.† The following cases may be of some interest to the profession in New York, as this mode of treatment is not generally resorted to by surgeons here, and indeed has only

* I exhibited these bones at the meeting of the N. Y. Ophth. Soc., in Nov., 1873.

† "The Use of Earth as a Topical Application in Surgery," by Addinell Hewson, M.D., one of the attending surgeons to the Pennsylvania Hospital, 1872.

been, I believe, but very imperfectly tried at Bellevue Hospital some three years ago.

CASE I.—A. G., a widow woman, keeping a boarding-house in the city, *et. 33*, a native of the United States, had been suffering for nearly two years from a varicose ulcer of the lower third of the left leg, on the inner side. Her appearance when I was called to see her was that of a healthy woman; but her history was imperfect, as she did not choose to be frank and candid with me. She was the mother of three healthy children. She had been attended by some physicians during this time, and all kinds of treatment, constitutional as well as local, had failed to produce any favorable impression on the ulcer, which finally became so painful as to cause her to confine herself to her bed. The patient informed me when I first saw her that she had noticed no great increase in the extent of the ulcer for the past eight months, but that it had gradually grown deeper, and that each day it was becoming more offensive. She had been in the habit of washing it carefully morning and night. When I first examined the leg the ulcer was as large as the palm of her hand, with callous edges, and a grayish, shroddly surface. The veins of the leg were considerably enlarged. At this time she had been confined to her bed for five days, and suffering great pain. I applied, at my first visit, iodoform in powder to the ulcer, strapped the part firmly, and bandaged the leg from the toes to the knee. I continued this treatment for five days, during which time the patient kept her bed, suffering great pain. The iodoform had the effect of cleaning off the sore nicely, but it showed no signs of healing at this time. The pain, however, which the iodoform produced was most intense, destroying her rest, and causing her continually to complain of burning in the leg. On the sixth day I gave up its use and applied dry earth. This gave her entire and immediate relief, and she passed the following night comfortably. She felt much refreshed on the following morning, and told me that she had felt no pain whatever in her leg since the application. She was in good spirits, had eaten a good breakfast, and seemed much encouraged. The dressing was then washed off with castile soap and warm water, the ulcer presenting a clean surface, and gave no pain whatever. I then applied earth, moistened with water, in the form of a paste, covered the part with waxed paper, and over this a firm and even strapping and a roller bandage. The patient was ordered to still keep her bed. No pain whatever succeeded the dressing. She rested well that night, and expressed herself as feeling perfectly comfortable on the following morning. On the next day, the fourth on which the earth had been used, I applied it in a fine powder, covered with waxed paper, strapped firmly, and applied the roller. Still no pain in the part. The next morning, at my visit, I found a bridge of tissue was forming across the centre; finely-powdered earth applied, and the dressing continued as before. Sixth day: bridge across the centre complete, and the part cicatrizing rapidly. The treatment was continued. On the eighth day of the use of the earth the patient begged to be allowed to leave her bed and occupy her lounge. I consented to this, and nothing unfavorable resulted from the indulgence; treatment continued. On the tenth day the ulcer was reduced to a small point, and under the daily application of the dry earth, dressing, washing, strapping, and bandaging, on the thirteenth day the cicatrization was complete.

CASE II.—J. F., a tinsmith, *et. 47*, came to my office and showed me a varicose ulcer of the left leg, of seven weeks' standing. The veins of the leg

were considerably enlarged. The ulcer was much inflamed, and very dirty. The patient was well nourished and healthy in appearance. He denied ever having had syphilis, but confessed that he had had gonorrhoea some ten years before. He was not intemperate, nor would he acknowledge himself guilty of any great excess. He was the father of two children, who had always enjoyed good health. I applied a dressing of wet earth, strapped the ulcer firmly and evenly, and a roller bandage from the toes to the knee; told him to go home and keep his bed. On measurement, the following morning, I found the ulcer to be $1\frac{1}{2} \times \frac{1}{4}$ inches. It was washed with castile soap and warm water, and dry earth, finely powdered, applied, strapped and bandaged as before. The ulcer had been giving the patient previously so much pain that he willingly had consented to give up his work and remain in bed. The pain had entirely ceased after the application of the earth; and on the following day I found him sitting up, and very comfortable, and feeling able, he said, to go back to his work. I kept him quiet, however, during the following four days, until, under the dressing and treatment, the cicatrization was complete.

CASE III.—Mr. J., from Boston, sent for me to visit him at his hotel (Hoffman House), and showed me a carbuncle which had been about two weeks developing itself. He was suffering intense pain, and was unable to obtain any sleep the previous night; indeed, he told me he had been able to obtain but little sleep during the entire time of its development. He had been applying poultices to it for more than a week. He did not claim to be a temperate man, but usually enjoyed good health. There was some pus coming out of two openings in the centre when I first saw him. The induration of the cellular tissue was considerable at its base. I made a crucial incision through the carbuncle, down to the healthy tissue beneath, without the use of an anæsthetic, and filled the wound with finely powdered dry earth. After the agony caused by the incision, the relief this application gave was very great. The patient slept soundly that night, and was sitting up on the following morning when I visited him. The earth was then washed off. The slough was seen to be protruding, and the tissues were contracting vigorously. I reapplied the dry earth, and retained it by a covering of waxed paper and a few straps. On the evening of the third day after the incisions were made, they had greatly diminished in extent. Dry earth was reapplied, and the wound dressed as before. On the fifth day I removed a portion of the core, as it was projecting, and dressed the wound with dry earth as before. On the seventh day, a clean excavated ulcer occupied the position of the carbuncle, and four days after, the surface had filled up to the level of the surrounding tissue. Cicatrization progressed rapidly under the same kind of dressing, and four days later the patient returned to Boston with all evidences of his former trouble removed, with the exception of a small granulating spot, which disappeared a few days after the patient reached his home.

66 WEST 36TH STREET, NEW YORK.

CASE OF LUMBAR HERNIA.

By WELLINGTON N. CAMPBELL, M.D.,

SENIOR ASSISTANT TO RECEPTION HOSPITAL, WEST 9TH ST., NEW YORK.
THOMAS WHELAN, four years of age, born in this city, was brought to the out-door dispensary of this hospital on the morning of November 22, 1873, for the treatment of an abscess, as the father called it.

We were directed to the spine as the seat of trouble, from the peculiar aspect of the patient, which is so characteristic of spinal disease. On examination was found a convex curvature of the spinal column, at about the middle of the dorsal vertebra, which was first noticed by his parents two years ago, and which very gradually increased in size. Eighteen months ago an abscess formed in the left loin, between the crest of the ilium and the last rib. After attaining a considerable size, it was lanced by a surgeon in attendance, and much pus discharged therefrom. A poultice was then applied, and it continued to discharge up to the 1st of last May, at which time they discontinued the poultice, and the wound closed. One month following the closure of the wound, another tumor made its appearance, which gradually increased, and the father, deeming it advisable to have it lanced as before, brought his child to this dispensary. The tumor was found to be situated at that point where the quadratus lumborum and latissimus dorsi intersect the external and internal oblique muscles. It was then about the size of a goose-egg, soft and fluctuating to the touch; tympanitic resonance was obtained on percussion, and, upon performing taxis forward and inward, it was reduced, followed by a rumbling or gurgling sound, reappearing upon the patient's coughing or making muscular exertion.

From these and other familiar signs it was diagnosed to be a lumbar hernia, due, in all probability, to disintegration of the muscular fibres of these muscles, owing to the long-continued discharge from the abscess above mentioned. After reduction was accomplished, a compress and bandage were applied to retain the intestine in place. The case was presented to Prof. Mott, at his clinic at Bellevue College, on the following Wednesday, and he confirmed the above diagnosis.

In looking over the literature of the subject, I find that Gross (System of Surgery) makes mention of but four cases of lumbar hernia, Holmes of one, and Erichsen of none. Gross, vol. 2d, page 559: "Lumbar hernia is extremely infrequent, the only cases hitherto reported being those of Petit, Pelletau, Cloquet, and Chapplain." Holmes: "In the third Bulletin Travaux de la Société de Médecine de Marseille, Dr. Chapplain* relates the case of a man, aged sixty, who, after being squeezed between a wall and a carriage, found in his loin a tumor, between the crest of the ilium and last rib. It appeared at first like a chronic abscess, but the presence of intestine was easily ascertained." Mr. Kingdon has seen a case of this kind; the bowels protruded just above the crest of the ilium at its highest point, about three inches from the spine, just where the quadratus and abdominal muscles meet. The man was forty-five years old, tall and thin. He suffered with hæmoptysis and emphysema of the lungs.

I take the liberty of publishing this case for three reasons. 1st, On account of its rarity. 2d, On account of the peculiar circumstances under which it occurred. 3d, The imminent danger that would necessarily follow the opening of a tumor of this nature.

ALBANY MEDICAL COLLEGE AND HOSPITAL.—Professors A. Van Derveer and J. M. Bigelow have resigned their respective chairs in this College, and also their positions in the hospital. Drs. John Swinburne and Thomas Becket have also resigned their positions in the latter institution. It is also reported that Professors Peaslee and Clymer, of this city, have declined to lecture in the College.

* One of the four cases mentioned in Gross.

Reports of Hospitals.

CHARITY HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

PNEUMONIA.

The remedies commonly employed in this hospital in the treatment of pneumonia are quinine, carbonate of ammonia, and the alcoholics; occasionally, if the fever is too brisk, liq. ammon. acetatis is administered. The oil-silk jacket is uniformly adopted. Quinine is administered from the beginning. Alcohol, as a rule, is early resorted to. Carbonate of ammonia comes in before the second stage becomes completely developed, and is continued throughout the remaining portion of the course. Diet includes hospital extras. An effort was made by one of the visiting physicians to withdraw, somewhat at least, from this highly tonic and stimulating plan of treatment. Accordingly, liq. ammon. acetatis and tincture of acopite were recommended as the chief remedies to be employed during the earlier part of the disease; but the experiment proved so disastrous, the rate of mortality increasing so rapidly, that the attempt at reformation was at once abandoned.

The constitutional condition of the patients who find admission to this hospital doubtless has a controlling influence upon the treatment necessary to be adopted in this class of diseases, if the best results would be obtained.

EXPECTORANT MIXTURE.

An expectorant mixture very commonly used in cases of chronic bronchitis, and with very good results, is the following:

R. Ammon. muriat.,
Liq. morph. sulph. (Mag.) ℥ss . . . ʒi.
Syr. tolu.
Syr. scillæ co., ℥ss ʒi.
M.
S. ʒi. t. i. d.

NIGHT-SWEATS OF PHTHISIS.

House-Physician Smith remarked that two-grain pills of oxide of zinc, t. i. d., has answered a better purpose in his division for controlling this symptom than any remedy that had been employed.

ACUTE ARTICULAR RHEUMATISM.

Dr. Smith also directed my attention to an external application to be used for the joints during the progress of this affection. The following is the formula:

R. Tr. opii ʒi.
Spts. chloroform ʒi.
Lin. saponis, ad Oi.
M.

This liniment is applied freely over the joints, and immediately covered with cotton and oil-silk. The relief from pain afforded by this application has been very gratifying to all his rheumatic patients. The general treatment is alkaline.

IRRITABLE STOMACHS.

The case to which my attention was directed was one in which the ordinary irritability of stomach associated with phthisis required special treatment. The method of treatment, however, is almost uniformly adopted when an irritable condition of the stomach manifests itself in connection with any chronic disease.

The remedy is *raw beef*, chopped fine and seasoned with salt, pepper, and vinegar. The patient is to subsist entirely upon beef prepared in this manner. Dr. Smith remarked that this plan had, in his wards, seldom failed to afford relief to this condition, when associated with any chronic affection.

SILICATE OF SODA IN THE TREATMENT OF FRACTURES.

House-Surgeon Pierce informed me that he had employed the silicate of soda in his division in the treatment of fractures equally as much as he had employed PLASTER-OF-PARIS. The soda splint has furnished very pleasing results, and, when carefully applied, makes a most elegant and serviceable splint. Three bandages are ordinarily used, the limb being coated over with the silicate after the application of each bandage. It is also well, and perhaps always advisable, to add narrow strips of pasteboard as the bandages are being applied. Extension, in the proper direction, must be maintained until the splint is thoroughly dried.

ACETIC SPRAY IN DIPHTHERIA.

Diphtheria, scarlet-fever, typhus and typhoid fevers, and small-pox, constitute a group by themselves.

By present arrangement this department falls under charge of the hospital staff, as one of the branches of "Out-door Service." Dr. Partridge, house-physician, mentioned that with regard to diphtheria very satisfactory results had been obtained in the local treatment of the disease by the use of acetic acid, in solutions of varying strength, in the form of spray. The remedy is used by means of the so-called atomizer. It seems to have the power to dissolve the membrane, and in several cases where well developed and somewhat advanced croupy symptoms were present, all were relieved, and that quite speedily, by the use of this agent. The administration of alcoholics is governed by the condition of pulse and temperature. The rate of mortality is small.

ITCHING AND PITTING IN SMALL-POX.

To relieve the intense itching which attends this eruption, washing the surface with glycerine and water acts as if by magic.

To prevent pitting, one of the visiting physicians recommended the use of tr. iodine. The remedy should be employed, if possible, before vesicles are formed. It is to be applied once a day. The effect of this remedy has not been sufficiently noted in the Small-pox Hospital to warrant any conclusions relative to its value in this direction.

It was used in one case after the eruption had been vesicular for one or two days, but before it had become pustular, and only a moderate amount of pitting followed. Whether the adoption of an *ectrotic* plan of treatment will not do the patient more harm than can be counterbalanced by the benefit arising from a moderate arrest of pitting, or even a complete prevention of pitting, is, in many cases, thought to be a question worthy of consideration.

To prevent the formation of abscesses, the combined hypophosphites have served a very excellent purpose. One patient had eight abscesses, and another four, at various situations upon the body, and all had rapidly headed under the influence of this combination treatment. In several instances threatened formation of abscess had been dispelled. The influence of this remedy, therefore, was looked upon with favor, for the reason that abscesses under such circumstances are not infrequently attended with *grave* results.

BELLEVUE HOSPITAL.

SECOND MEDICAL DIVISION. DR. FARRINGTON, HOUSE-PHYSICIAN.

HEMORRHAGES.

This class of difficulties, such as hæmoptysis, hæmorrhage from bowels, hæmaturia, hæmatemesis, and hæmorrhages from the uterus, are treated upon this division most satisfactorily by the use of spirits of turpentine. The remedy is commonly administered in ten-drop doses, repeated every two hours.

IODIDE OF POTASSIUM IN ANEURISM.

Our attention was directed to a case of thoracic aneurism, in which nearly all the distressing symptoms had disappeared since the patient had been placed upon large doses of iodide of potassium.

CHRONIC BRIGHT'S DISEASE.

The water-treatment for this affection, referred to in another report, is at present regularly adopted, and the patients do exceedingly well.

If vomiting is developed, ice taken by the mouth constitutes the main reliance for its arrest.

If headache is present, hypodermics of morphine are administered.

If convulsions are threatened or developed, hypodermics of morphine are resorted to for their control.

In general, the diet of the patient is to be sustaining, and milk is a most excellent article of diet, if it can be obtained pure.

PNEUMONIA.

Quinia will reduce the temperature and pulse of pneumonia with a good deal of certainty.

Such an effect is beneficial.

It requires large doses to accomplish this. It is customary to give pneumonic patients grs. x. in the morning, and grs. xv. at night, or grs. x. morning and night.

CARBOLIC-ACID OINTMENT FOR SCABIES.

Its success warrants farther trial.

MONARTHRITIC CASE.

Cardiac complication had occurred since admission to the hospital.

The case shows the importance of correct diagnosis, in order that the patient may receive the greatest benefit from treatment.

HEMORRHAGE FROM THE LUNGS.

There were some features of interest in connection with this case. The patient was æt. 28, single, and a domestic. Mother died of consumption. One year previous to her admission, suffered from a sudden attack of hæmorrhage from the lungs. Soon after she began to lose strength, had night-sweats, and lost her appetite. Pain, especially beneath the scapula. Has suffered from several severe hæmorrhages. She has mitral regurgitation.

Hæmoptysis with mitral regurgitation is a point of interest.

Mitral obstruction is the usual cause of hæmoptysis when dependent upon cardiac disease.

If the hæmorrhages are profuse, it is hardly warrantable to conclude that they are due to cardiac lesion.

If regurgitant lesion alone exists, it is never warrantable to say that the hæmoptysis is dependent upon a cardiac cause.

The patient has improved since her admission to the hospital.

IMPROVEMENT IN A CASE WHERE THERE HAS BEEN REPEATED AND PROFUSE HEMORRHAGES FROM THE LUNGS.

This is another point of interest.

In general, patients do better when hemorrhages from the lungs occur, if they are phthisical patients, and they are also rather more likely to recover than those who do not have such hemorrhages; or, if they do not recover, they are apt to have an arrest of the disease. These facts can be used for the encouragement of patients.

Such were some of the interesting features of the case we were visiting, as drawn out by the Visiting Physician.

SURGICAL DIVISION.

FRACTURE OF FOREARM.

The case was one in which an old fracture had united with great deformity. The patient was placed under the influence of ether, and the bones were rebroken.

The following dressing was applied, which Prof. Sayre employs in the treatment of all fractures of the forearm. First, prepare two pieces of board (cigar-box answers a good purpose), somewhat wider than the forearm, and of sufficient length to reach from the palmar surface of the hand to near the flexure of the elbow. Next, prepare two pads of adhesive plaster for the interosseous spaces, which is done by rolling adhesive plaster, with the plaster side out, until a pad or roll is obtained about half an inch in thickness. These are to be of the same length of the forearm. Next, prepare two compresses of adhesive plaster, plaster side out, and two inches square, which are to be applied above and below the point of fracture. Next cut two long strips of adhesive plaster, which are to be used in retaining the splints in position.

The apparatus is now ready for adjustment. It is adjusted in the following manner: place the forearm at right angles with the arm, with the palm of the hand looking towards the mouth of the patient. Next, direct an assistant to take hold of the arm, just above the elbow, for the purpose of making counter-extension; then you will yourself, or have an assistant, seize the hand, and make extension until the bones are placed in their proper position and hold fast. One roll or pad of adhesive plaster is now to be placed over the interosseous space upon the anterior aspect of the forearm, and the remaining pad or roll is to be placed in a corresponding position upon the posterior aspect. Next, place one of the square compresses just above the fracture anteriorly, and the other just below it posteriorly. These compresses are to be placed over the interosseous pad or roll. Then place the two pieces of board immediately against the two interosseous pads upon the forearm, and secure them snugly at the upper and lower extremities, and perhaps at the middle portion, with the long strips of adhesive plaster. The splints are to be applied immediately over the adhesive pads and compresses, without any covering whatever. In this way they are held firmly in position by the adhesive plaster. The principle involved in the treatment of this fracture, says the Professor, "is that which should guide you in the treatment of all fractures, namely, extension and counter-extension in the proper direction until the muscles adjust the broken fragments with perfect accuracy, and then no more extension and counter-extension, but retention."

ARMY STAFF RANK.—The New York Academy of Medicine, New York Pathological and New York County Societies, and New York Medical Library Association, have passed resolutions favoring the Army Medical Staff Rank Bill.

BROOKLYN CITY HOSPITAL, BROOKLYN, N. Y.

COMPOUND DISLOCATION OF RIGHT KNEE.

While the patient was aloft, adjusting some machinery, he was caught by a revolving wheel, throwing him some distance; picked up with the above injury.

The displacement was tibia and fibula forwards, femur backwards, condyles exposed through popliteal space. Three (3) inches shortening, arterial circulation of leg intact, muscles of the thigh were in a very flaccid condition.

Dr. Speir amputated at thigh.

COMPOUND DISLOCATION OF RIGHT ASTRAGALUS.

The injury was received from patient slipping upon sidewalk, foot being twisted in, astragalus thrown forwards and outwards; considerable laceration of tissues. Patient was not admitted into the hospital until eight days after reception of the accident, the limb then presenting an unhealthy condition. Dislocation unreduced.

Dr. Speir resected the astragalus. There is now slight motion between the os calcis and tibia, and the patient is improving in the use of the foot.

DISLOCATION OF SIXTH AND SEVENTH DORSAL VERTEBRÆ.

In speaking of serious dislocations, there is one of the above in the house. The accident was received from falling through five (5) hatchways. No other injury was sustained. He presents all the symptoms of this lamentable accident, but has now been lying upon a water-bed for 90 days, and to all appearances is in a far better condition than he was one month ago. The patient is kept partly under the influence of morphia.

FRACTURE OF BASE OF SKULL, RUPTURE OF MIDDLE MENINGEAL ARTERY, AND MENINGITIS, CAUSED BY A FALL OF FORTY-FIVE FEET.

The interesting fact in this case was the entire absence of all signs of compression until five (5) days after admission, the day before he died, when slight stertorous breathing, with facial paralysis, and anesthesia of the eye, pupils moderately dilated, were noticeable, and finally complete coma, in which the patient died. Autopsy revealed comminuted fracture of petrous bone and fracture at base, with clot outside the dura mater, at the point of rupture of middle meningeal artery. The fluid discharged from ear was spinal in character.

FRACTURE OF STERNUM.

There is one case of this kind in the hospital at present. The accident was received from caving in of an embankment. The seat of fracture is at the articulation of the manubrium and gladiolus, the upper portion being considerably displaced backwards.

It is treated by a compress and roller bandage surrounding chest and that portion of sternum below the fracture, so as to enable the respiration to be abdominal as much as possible.

FRACTURE OF PATELLA.

The method of treatment at present is to keep the leg well elevated, and, as soon as the inflammation has subsided sufficiently, place a small pad surrounding the fractured patella. A broad piece of adhesive plaster, its lower border cut to fit the upper margin of the patella, with two straps sewed to it, is fastened to the anterior aspect of the thigh. A similar piece is applied to the leg, with buckles attached.

By means of the strap and buckles the fragments are kept in apposition, and as the swelling subsides they are gradually tightened.

The leg is kept in this manner, well elevated, for at least three (3) weeks, when a strong posterior plaster splint is applied.

We have one case in the wards who has had 3 consecutive fractures of the same patella within the past six (6) years.

FRACTURE OF SUPERIOR MAXILLA.

A particular feature in one of the cases was the amount of displacement, and the good result obtained by wiring the teeth and placing a gutta-percha splint between the upper lip and superior maxilla. The ends of wire from the teeth were brought through holes in the splint, and twisted to one another upon its anterior surface.

The patient has good use of both maxillæ during the treatment.

FRACTURE OF FEMUR.

Noticing Buck's extension and the quadruple splint in the wards, reminds us of the fact that, during the present service, and from past experience, better results are obtained than in the hurried application of plaster splints.

FRACTURE OF TIBIA AND FIBULA.

Our attention is called to five cases. The method of treatment in these, as well as in all other fractures, is to wait until the swelling has subsided, and then apply plaster splints, which, by the way, have been used in this hospital for the past eight or nine years. In these particular cases anterior and posterior splints of a reasonable thickness are employed; the patient finds the plaster more acceptable to the skin than anything which you can interpose; he is then enjoined to keep quiet, as the disposition to move round does not benefit the case.

COMPOUND FRACTURE OF TIBIA AND FIBULA.

Among compound fractures we notice one of the tibia and fibula, leg being placed in the hospital swing, which is well adapted for the purpose. It consists of an iron frame, the leg suspended and resting upon muslin strips, which can be changed and kept free from all discharges without disturbing the leg.

ESMARCH'S METHOD.

Esmarch's method of operating was performed by Dr. Speir in removal of the first row of carpal bones, for necrosis. The entire absence of blood certainly simplified the operation, and it remains to be seen if the result justifies it. In sprains, with subacute inflammation of the joint, nitrate of potash, in 20-grain doses, three times daily, is found serviceable, and in indurated swellings the following ointment has been used successfully:

Unguent potass. iodidii,
" belladonnæ, ʒi. ʒss.

or
B. Liniment sapon. camph. ʒiv.
Potass. iodidi ʒii.
Tinct. belladonnæ ʒss.

Erysipelas is successfully treated by large doses of mur. tr. of iron and the lead and opium wash.

"Styptic cotton" has been used in this hospital for some time, and has been found useful as an antiseptic dressing in compound fractures, also in arresting hemorrhage. It is frequently applied to indolent ulcers and excoriated surfaces (after first scarifying them), to secure healing by scabbing.

Skin-grafting has met with very good results in this hospital.

Strictures of the urethra are treated, during the present service, by internal division with the urethrotome.

In closing wounds, the hare-lip suture is used in preference to silver wire or silk.

Several cases of abdominal aneurism have been successfully treated by the administration of gallic acid ʒss. and liq. ferri subsulphatis gtt. iv., three times a day alternated. During the present service Speir's artery-constrictor is used in closing arteries after amputations, etc.

The aspirator was recently used in removal of fluid from the knee-joint, with good result.

Progress of Medical Science.

CONTRIBUTION TO THE STUDY OF EMETICS.—A hypodermic injection of free emetine causes vomiting, and the emetine is detected in the stomach and in the vomited matters. The vomiting does not take place until after three times as long a period as when given by the mouth. Heilmann and Simouowitsch have obtained analogous results on introducing the emetine into the veins. The vomiting takes place by reflex action; the centripetal arch is most frequently formed by the pneumogastric. The first impression is formed by emetine on the gastric extremities of this nerve. The centripetal arch follows the course of the glossopharyngeal when there is nausea, but follows another when the vomiting originates in the brain, as from bad odors, etc.

The action of the pneumogastrics is demonstrated, first, by the vomiting which immediately and constantly follows irritation of the central extremity; second, by retardation and suppression of vomiting when the experiment is made upon a dog whose pneumogastrics have been cut. If in such cases the vomiting is not suppressed, it is because the deficiency of the pneumogastrics is supplied, and the centripetal arch of innervation is completed by the great sympathetic. "The centrifugal arch is supplied by the great sympathetic, and it probably has its centre of reflection in the solar plexus."—*Lo Sperimentale*, 10, 1873.

LIME-SUGAR GLYCERINE.—Latour had occasion to try this new lime liniment on a number of patients, wounded by an explosion at Mont Valérien, and with especially good results. Entasis's saccharate of lime is almost equally soluble in water and glycerine, in the latter in the proportion of about 36 per cent.; but the aqueous solution is coagulated by heat, which does not take place with the glycerine solution. Instead of using the dry saccharate of lime, Latour makes a nearly saturated solution of the saccharate in the following manner:

Calc. oxid. hydrat.	gram. 200
P. sacchar.	" 400
Aquæ	" 2,000
Glycerini.	" 400

The lime and sugar are well mixed in a mortar, and water slowly added till a clear homogeneous paste is obtained. The mixture is placed in a well-corked flask, and allowed to stand for twenty-four hours. It is then filtered, the glycerine added, and evaporated to one litre. The glycerine does not coagulate by boiling unless it has been diluted with four volumes of water. Placed on the skin, the mixture forms a sort of varnish,

and causes a pleasant sensation of coolness on the inflamed surfaces.

The new lime liniment is prepared by mixing one part of the above-mentioned dilute solution, before evaporation, with two parts of olive-oil. A mixture which is not so thick is obtained by using almond-oil in place of olive-oil. Where there is considerable suppuration, camphor-oil may be added to diminish the fetid smell.

Dr. Lagarde has found the liniment useful for burns, and Dr. Müller, for erysipelas of the face. Lator maintains that it may be advantageously used in other cases, where the skin is the seat of more or less severe inflammatory symptoms, as in erythema, frost-bite, variola, and various eruptions.—*Report de Pharmacie et Hôpitals, Tidende*, Jan. 14th, 1874.

MEDICATED GELATINE.—Disks of gelatine, impregnated with atropine, calabar bean, etc., have been used for a long time, and it has been found that the dose thus administered could be readily and accurately determined by the size of the disks. In Sweden, since 1870, many other remedies have been prepared in this way. The sheets of impregnated gelatine, marked in small squares, containing a determined amount of the medicine, are put up in envelopes, which are marked with the name and dose of the remedy. The medicines most commonly used may thus be carried in a small pocket-case and dispensed by the physician.

At a meeting of the Swedish Medical Society, on the 21st of October last, Dr. Edholm made a report on the use of Prof. Almén's medicated gelatine by the Swedish polar expedition of 1872-73. This method of administering medicines was found very convenient and efficient. Many specimens were exposed to all varieties of temperature, as well as to extreme moisture and dryness, but at the termination of the expedition, which lasted fifteen months, they were found to have retained their original condition and therapeutic properties unimpaired. In using the disks, the prescribed number are placed on the tongue and swallowed with the aid of a little water. They are quite tasteless.

SERO-ALBUMINOUS EPISTAXIS.—In the recent discussion on Albuminous Expectoration at the Société Méd. des Hôp., analogous cases of epistaxis were cited. The following is a new case in point: a man, aged fifty, well made, suffering from hemorrhoids, without any previous weakness or malady, is taken from time to time, suddenly and without appreciable cause, with an abundant nasal flux. The liquid is sero-albuminous, limpid, insipid, inodorous. The flux is preceded and accompanied by pruritus of the nasal mucous membrane; it takes place from the nostrils, and occurs several times in the day. Injections and inhalations of salt-water suffice to arrest the flux, which has several times been cured by the same method.—*Gazette Méd. and Mouvement Méd.*

NON-MECHANICAL TREATMENT OF PROLAPUS UTERI.—Dr. Andreef having noticed that tincture of iodine applied to the uterus is capable of rendering the ligaments firm and tense, has tried this remedy in prolapsus uteri. The results appear to be quite satisfactory in the cases he has published. The simplicity and innocence of the treatment should lead to its adoption by others. The first case was that of a young woman who had had prolapsus for four years. The organ was replaced by means of the speculum, and a gramme and a half of the official alcoholic tincture, slightly diluted with alcohol, was applied to the roof of the vagina. The patient maintained a horizontal position in bed for several days, and made four injections of warm water each day. The operation was repeated every

three days for four times, the tincture being more and more diluted each time. The patient was completely cured.

The author states that from two to six applications of the tincture are usually sufficient. If complicating diseases exist, they are to be first cured. The tincture is to be applied to the roof of the vagina only, and the patient should remain in bed during the first two applications; during the remainder of the treatment it is necessary to merely abstain from fatiguing occupations, walking, etc. The bowels should be kept open.—*Riv. di Med., di Chir. e di Ter., and Nuova Liguria Med.*, 30, 1873.

TREATMENT OF ANGINA PECTORIS.—Dr. Hueber, of Lioland, believes that the only permanent relief for angina pectoris is to be obtained through the galvanic battery. In most cases of this kind, where auscultation and percussion reveal no material change in the heart, the phenomena are so characteristic of nervous affections that the disease should be regarded as a nervous one. The cardiac plexus is the seat of the difficulty, and hyperæsthesia provokes the alarming train of symptoms.

In an obstinate case which came under his care, Dr. Hueber employed a number of remedies without success, and finally had recourse to the galvanic current.

He employed Stohrer's battery with thirty elements. The cord was found intact, but on applying the current over the sympathetic, only four elements were borne on the left side, and six on the right. After the first sitting, the attacks ceased, and never returned. The patient was soon able to bear six elements on the left side, and eight on the right; and finally, an equal number could be applied on both sides. Thirteen applications in all were made. It is proper to add that the valerianate of quinine was continued without interruption at the same time, though from previous experiences it was not believed to have effected the permanent cure.—*Deutsche Archiv f. Klin. Med., Allg. Wien. Med. Ztg.*, 2, 1874.

New York, March 16, 1874.

THE ARMY MEDICAL STAFF BILL.

THE hearty endorsement by the profession of the "Bill to Promote the Efficiency of the Medical Department of the United States Army," is nothing more than could have been expected. It is eminently proper that this should be the case, as no body of men are capable of expressing an opinion upon a subject which is of such a purely professional character, which involves so many questions of professional qualifications, professional emoluments, and professional honors.

Ever since the Memorial from the American Medical Association was presented to Congress, we have advocated the measures proposed, and shall continue so to do so long as the bill is *sub judice*. The whole matter merits discussion, and the profession are more than willing that it should be discussed, confident that nothing but good can come of such a course in affording opportunity for the presentation of facts which are able to speak for themselves in the interest of truth and in the cause of justice.

Thus far an encouraging progress has been made in the required direction. The committee having the bill in charge have shown a commendable willingness to be guided by the suggestions, to be convinced by the arguments, and to be impressed by the facts which have been offered in favor of the passage of said bill.

The questions of the necessity of the change proposed, of the utility of the measures urged, have been and are still the main ones upon which its final success must be determined. These are obstacles which, in the main, apply to the passage of every bill; but it is especially the case in the present instance, as it has been claimed that the medical department is as good as it can be made; that good men have always been found in the medical profession to keep the Army Medical Staff to its present standard; that the compensation has heretofore been satisfactory; and that the country's

requirements for economy are incompatible with the increased expenditure involved.

These objections can be met satisfactorily, we believe, by the discussion of the general subject under the following heads:

I. What are the duties of our army surgeons?

II. What sort of men are required to perform these duties?

III. What are the services of such men really worth?

I. The army surgeon is responsible to the government for the health, and often for the lives, of our soldiers, officers, and their families. In discharging such weighty responsibilities he must rely on his individual skill and knowledge in any and every emergency, rarely having the opportunity of consulting with others of his profession, as in civil practice. He is expected to be a good obstetrician, a skilful physician, a successful surgeon, ready to undertake any operation without professional assistance, to face an epidemic, to organize a system of quarantine, to conduct a difficult labor, or to build and conduct a hospital. He must needs be a practical hygienist, liable at any time for an opinion as to the healthfulness of a particular locality at a particular time; as to means to be adopted to prevent the spread of an epidemic; to examine and decide upon a proper water supply; to provide suitable means of disinfection, and to guard against malaria.

II. In view of these requirements, and in view of the faithful and conscientious discharge of the duties of his office, the answer to the second question can be readily anticipated. In a word, the army surgeon must be a thoroughly educated, scientific medical man, and such qualifications must be guaranteed by a strict and thorough examination before he is allowed to enter the corps. The standard of requirements cannot possibly be lowered, if the best educated medical men are needed.

III. The answer to the third question, "How much are the services of such men really worth?" is one which has a very important bearing. It is no doubt possible that the government might get physicians for one hundred dollars a month, and it is certain that it could not get some of our physicians for six times that amount. Practising in one locality, with a home, friends, and the conveniences of civilization, is a very different thing from the life of a medical officer who must break up his little establishment about once in two years on the average, selling what he can, and giving or throwing away the rest, to obey an order to report to some distant post, perhaps to meet an epidemic, to be separated from his family, or to take what is technically termed "the risks of war"—the risks with none of the honors. The question resolves itself into one of demand and supply, and we are willing to view it from such a standpoint. The value of services can only be measured by the amount of compensation they can command in open market. A physician in civil practice, after his first five years, can generally

command a living income for himself and family, which income steadily increases with his reputation, until, at the end of twenty years, it will average five or six thousand per annum. We make this average low purposely, to make it apply to physicians all over the country, and for the reason that we wish to be understood as speaking entirely within bounds when we assert that such is an ordinary success for a skilled practitioner anywhere. In this estimate we leave out of consideration the incomes of some of our leading metropolitan practitioners of twenty years' practice, whose earnings vary from ten to twenty thousand per annum.

Let us contrast these amounts with the pay of the army surgeon, who must be acknowledged to represent a high type of professional intelligence and ability:

Pay on entering service, and for three years after, per annum	\$1,600
Pay after three years, and up to an average of fifteen years' service.....	2,000
Pay after fifteen years service (rank of major).....	2,500

In addition to the above, ten per cent. is allowed for each five years of service. When disabled by age or disease, these gentlemen can be retired on three-quarters of the above rates.

The opinion of the Surgeon-General, endorsed by every medical man in the land, is that the inducements now offered by the government are not sufficient to retain such men in service as ought to be employed.

This opinion is based upon the following significant statement:

Number of medical officers in the United States Army, January 1, 1865.....	163
Number of medical officers in the United States Army, added since January 1, 1865.....	79
	—
	242
Medical officers who have resigned since January 1, 1865.....	48

It will be seen that almost twenty per cent. of the corps have, during the time named, resigned. The reason is quite obvious. They could surely do much better in civil practice. We could name many striking examples of this sort which have come under our own observation in this city, every one of which, by the remarkable success in private practice, proves the army surgeon to be a thoroughly competent practitioner.

The present request of the army medical officer is certainly a very modest one under the circumstances, and must needs commend itself to the most rigid economist in the House. The army surgeons are seemingly content with the present rate of pay for twenty years, but after that they ask that the rate be three thousand a year, and after thirty years' service (!) that it may be thirty-five hundred per annum, the reason for the latter modest request being, that when they are retired, which happens very soon after, they may then receive

twenty-six hundred and twenty-five per year; and this is all that the faithful army surgeon can hope to look forward to in his old age. It is certainly a reflection upon our government that such a request should be necessary, much less that there should be any doubt of its being granted.

If none of the changes contemplated in the bill are made, the government must expect to hear of more resignations, must calculate upon having the vacancies thus created filled either by physicians employed by the month, or by freshly graduated men. To none others would it be an advantage to enter the service. The income of a young physician, just starting in practice, is always exceedingly small, and the salary of an assistant surgeon is a temptation to any worthy and young medical man who wishes to bridge over the pecuniary trials of the first five years. After that time he is aware that he is at a standstill; in fact, that every year he remains in the corps is a pecuniary detriment to him; consequently, just at the time when his services begin to be really valuable to the government, he is forced to offer his resignation. If it be economy on the part of the government to encourage such a practice, we are at a loss to see wherein it is the gainer. The policy should be to offer such inducements to the best educated medical men, not only to enter the army, but to remain in it; and this end can only be attained by a regular increase in pay and a corresponding increase of rank and honors.

The profession at large are interested in this matter in two ways. As a body of citizens specially qualified to judge of the medical wants of the army and of the country, it urges the adoption of measures to secure and retain the best medical talent in the land; as a body of professional men, it has a just pride in seeing itself well represented in the service of its country. The latter consideration is especially important in view of the valuable services which these men may, under the patronage of the government, render to medical science in general. There are medical problems which can be worked out to no better advantage than by that very concentration of intellectual force and well-regulated system which can only obtain in a well-organized and well-disciplined corps. Let us take a single instance in passing. The army surgeons, scattered all over the country, are ordered to report their observations, and work upon a common plan, and report to a central head. In no other organization of medical men could such a concentration of work be accomplished, and in no other way could such valuable reports be made available to science and humanity.

In order to show the relation the medical officers of our army bear to the same officers of the English army as to rank (and consequently pay), and also to the other staff corps of the army and navy, we have taken pains to present the following table, which speaks for itself:

MEDICAL DEPARTMENT.

	Major-General.	Brig.-General.	Colonel.	Lt.-Colonel.	Major.	Captain.	Lieut.	Total.	Ratio to Whole Number of Active and Retired		Ratio of Whole Number of Active Officers.

Can we do more, in conclusion, than speak, on the behalf of the medical profession of the United States, in terms of unqualified approval of the bill now before the committee?

ALUMNI ASSOCIATIONS.

THE various medical Alumni Associations of our city appear to be actuated alike with the desire to promote friendly intercourse among their members and to advance the cause of medical education in their respective schools. Subscriptions are already started for the establishment of a fund for the endowment of extra professorial chairs, and the success which has so far rewarded the efforts in this direction are substantial evidences of hope for the future. An important recognition of the influence of the Alumni Associations is given in the recent action of one of the faculties in allowing the President of its Alumni Association to be a member of the board of trustees. This is a matter of right which we have long ago insisted upon. We hope soon to hear that other college faculties have followed this commendable example.

HOSPITAL APPOINTMENTS.

In a recent after-dinner speech at one of the college reunions, Mr. Stern, one of the Commissioners of Charities and Correction, acknowledged that the present method of appointing physicians to the hospitals was faulty in so far as it left the choice to laymen, and he was inclined to the opinion that the profession alone should have a voice in the matter. This is what we have many years contended for. We should like to hear of a practical plan from Commissioner Stern upon which such appointments could be made.

OUR PUBLIC SCHOOLS.

THE daily press is giving considerable attention to the discussion of the question of the physical welfare of school children. One paper calls attention to the bad effects of insufficient light, another to bad ventilation, etc., all agreeing that a reform is necessary. The initiation of such a reform would be to appoint a medical man upon the Board of Education, and thus pave the way for the establishment of proper sanitary inspection and hygienic regulations. It must come to this at last, if any reasonable reform is contemplated.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF KINGS, N. Y.

DISCUSSION OF THE THERAPEUTIC VALUE OF VERATRUM VIRIDE IN PUERPERAL CONVULSIONS AND OTHER SPASMODIC DISEASES.

This subject was before the Society at three meetings within the past twelve months—two in May, one in January. The report is necessarily greatly condensed, and is arranged rather according to the subject-matters discussed, than to the exact order of the remarks in point of time; precedence being given to the treatment of puerperal convulsions.

CASES OF PUERPERAL CONVULSIONS TREATED BY VERATRUM VIRIDE.

CASE I. By DR. COREY.—Mrs. H., æt. 19, primipara, robust and of full habit, delivered at term at 10 A.M., the labor natural, and presented no untoward symptoms. At 11 P.M., without any premonitory symptoms, a violent convulsion occurred, which was soon followed by others, each of which was represented by friends as more severe than the preceding one.

In the absence of the attending physician, I was

summoned at 4 A.M. Found the patient insensible and struggling violently with her friends; face flushed; head hot; pulse 130 per minute, full and strong. Desiring to test the action of veratrum viride in such cases, I determined to rely wholly upon this agent, and began by giving 15 drops of the official tincture every fifteen minutes. No perceptible effect being produced upon the pulse at the end of an hour, I gave 20 drops as before, once in fifteen minutes, which reduced the pulse to 98 during the second hour.

At 3 o'clock a sixth convulsion occurred. As soon as the patient could be made to swallow, I gave $\frac{1}{2}$ teaspoonful of the tincture, which caused slight nausea, free perspiration, and reduced the pulse to 78 per minute, when I repeated 20 drops every fifteen minutes, until the pulse was reduced to 65; after that the remedy was given at longer intervals, but sufficiently often to keep up a free perspiration.

At 5 o'clock the pulse suddenly increased in frequency, and was followed by another convulsion, the seventh, which was less severe than the previous ones, but strongly marked; 20 drops of the tincture was given, which promptly reduced the pulse to 58, and caused complete relaxation, with free perspiration and vomiting. Occasional doses of ten drops now served to keep the pulse below 60 until 7 o'clock, when, no convulsion occurring, I left the patient, directing 10 drops to be given once in fifteen minutes, unless vomiting should occur, in which case it was to be discontinued.

Returning at 9 A.M. I found that a single dose only had been given, because, as the mother said, "she seemed so sick to her stomach," and that a slight convulsion (the eighth) had just occurred. A single dose of 20 drops of the tincture at once brought the pulse down to 55, and again induced free perspiration.

During the night the kidneys had acted freely, and the bowels moved twice. At this time, 9 A.M., the patient seemed partially conscious, and as she complained of headache, it was determined to supplement the veratrum by a brisk cathartic, for which purpose $\frac{1}{2}$ grain elaterium was given. Free catharsis followed, with marked relief of headache. The patient had no more convulsions, and made a speedy recovery, having taken in all 5 drachms of the official tincture.

CASE II.—Mrs. G., primipara, æt. 21, in early life an epileptic, plethoric and anasarous; urine highly albuminous; labor normal and terminated in five hours. At 9 A.M. patient seemed inclined to sleep, but drowsiness was attributed to chloroform used to facilitate labor. At 11 A.M. a convulsion occurred, and was represented by the nurse as "very severe;" at 12.30 there was a second, not so violent. At 12.40, when I first saw her, she was comatose; pulse 98. At once gave her 10 drops of Squibb's fluid extract of veratrum viride. At 1, patient profoundly comatose, pulse 120, face suffused, head hot; repeated dose. At 1.30, pulse 100, gave 10 drops more. At 2, pulse 80, no nausea, but skin somewhat relaxed; gave 10 drops more. At 2.30, pulse 66, slight nausea, with free perspiration. At 3, pulse 58, sleeping heavily, but can easily be roused so as to recognize friends and swallow nourishment; relaxation complete; free perspiration; this continued for the next two hours. Forty drops of the extract were taken in less than an hour and a half. At 5, urine was drawn and found highly albuminous. At 7.30, perspiring freely, slight vomiting. The night following passed comfortably, patient gradually regained consciousness, and speedily recovered without return of convulsions.

CASE III. By Dr. RUSHMORE.—Mrs. W., æt. 22, primipara, was delivered at about 1 P.M., March 25, 1873,

at full term, of a healthy male child. I first saw her during the second stage of labor, and learned that she had suffered much from dyspeptic symptoms and oedema of ankles during the last two months of pregnancy. At 8.15 P.M., after several hours' severe and throbbing headache, she had a convulsion, which the nurse said lasted ten minutes. At the suggestion of Dr. Hutchison, who saw the case with me, twenty drops of Squibb's fluid extract of veratrum viride were administered by the mouth, and repeated every twenty minutes until 10.5 P.M., when she had a second convulsion. After the first convulsion, the pulse came down gradually from 100 to 76 beats per minute, and was reduced materially also in force; there was almost complete loss of sight, which continued until the following evening. Chloroform was administered during the second and third convulsions, but did not seem to shorten their duration. After the second convulsion patient vomited freely, and the pulse ran down to 60, when I ventured to decrease the dose to fifteen drops. The pulse increased in frequency, and at 1.45 A.M., March 26, she had a third convulsion less severe than the preceding. Patient still complains of her head, and is perspiring freely. At 4 A.M. she had the fourth and last convulsion, of short duration, followed by deep sleep with stertorous breathing. At 5.50 found the urine (the first that could be obtained) highly albuminous. The bowels were freely moved by the use of croton-oil, and the pulse, under fifteen-drop doses of veratrum given every half hour, fell to 55 at 2 P.M., and from the next dose at 4.30, to 48, the temperature being 98°. A single ten-drop dose was given at 10 o'clock, and then omitted, the patient having taken, in all, 483 drops in about twenty-six hours. The sight returned slowly after 10 o'clock, and on the following morning patient was free from headache, having slept well during the night, though feeling still weak. Her pulse was beating at the rate of 60 per minute. Of course the patient had been nourished by the use of beef-tea, milk, &c. The urine, which contained no casts, in the course of two weeks was entirely free from albumen, and with the exception of a mammary abscess during the following week, the patient made a good recovery.

CASE IV. By Dr. FEARN.—Sept. 5, 1871, I was called by Dr. Teller to take charge of a case of puerperal convulsions occurring in an Italian patient about twenty-five years of age, and a primipara. She had been suffering from headache, great nervous excitement, and general anasarca. The doctor ordered three comp. cath. pills, and at 6 $\frac{1}{2}$ P.M. bled her copiously; but the convulsions did not cease. He then ordered half-teaspoonful doses of tincture veratrum every two hours. When I arrived, at about 9 P.M., she had not had a convulsion for nearly an hour. Shortly after my arrival she had another convulsion. After it had passed off, the pulse was 108 and firm. I then ordered the same dose repeated every half-hour until 2 A.M. of the 6th, at which time the pulse came down to 80, and the same dose ordered to be continued every hour. At 3 A.M. she vomited freely, and passed a small quantity of urine. I then had the dose reduced to one-fourth of a teaspoonful, to be repeated every hour as before. At 4 A.M. I was aroused to find her in a very severe convulsion, from which she never rallied, and died at 11 $\frac{1}{2}$ A.M. All our efforts to excite premature labor were unsuccessful.

Remarks.—In the case related above, the patient being unable to speak or understand the English language, we were not able to do much with her except by force. But the case clearly shows veratrum to be more efficient than blood-letting, for there were six

hours between the convulsions after the veratrum was administered freely.

CASE V.—By DR. W. H. THAYER.—Mrs. A., aged 25, married two years, primipara, was first seen May 3, 1873, in consultation with Dr. Geo. I. Bennet. Gestation had progressed to full term, with little disturbance besides oedema of lower limbs. Urine not examined. On the 2d of May had symptoms of "indigestion," as vomiting and cramp in stomach. At 4 A.M. the next morning convulsions set in, and when seen, at 9 A.M., there had been five severe and protracted seizures, marked by frothing at mouth, lividity of face, unconsciousness, and stertorous coma. Pupils dilated; pulse 120, tense, but not full; in the first stage of labor. As she had been treated by tartar emetic, and venesection (about four ounces taken), and large sinapisms, without benefit, treatment by veratrum was substituted, and at 9.40 A.M., one drachm of Norwood's tincture was given. After this she had only two convulsions, at 10 and 11 P.M. The pulse was reduced to 60, and soft; vomiting continued nearly one hour. Labor terminated at 2.30 P.M.; child dead. Recovery.

Note.—This case is valuable by reason of the sharp contrast afforded between the vigorous antiphlogistic measures so long in vogue, and the treatment by veratrum. The former appeared to have no remedial power, while the latter was followed by entire relief, although labor was still in progress, and delivery not accomplished until three hours later.

CASE VI.—Veratrum alone employed. Mrs. S., æt. 32, married five years, primipara; of excitable temperament; a vegetarian; generally constipated and has dysmenorrhœa. Has had oedema of feet for two months; urine free. At 8 A.M., June 19, 1873, labor began, with considerable hemorrhage, ovum separated by clots. Premature labor induced; terminated at 6.15 P.M. Passed a quiet night, but at 11 A.M. (June 20) was taken with a violent convulsion, the first and only one. Pulse almost imperceptible, and respiration was much obstructed.

At 11.30, when not fully restored to consciousness, administered extracti veratri viridis gtt. xx.; pulse 104, full and strong. 11.45, extract. ver. vir. gtt. xxv. 12 M., pulse same, ext. v. v. gtt. xxx. 12.10, pulse 88; asleep. 12.15, pulse 100; patient uneasy; slight twitching of one side of face. Extract. ver. vir. gtt. xxx. 12.30, pulse 81; asleep. 12.50, pulse 72. 1 P.M. extracti ver. vir. gtt. xxx; more than two drachms in less than two hours. At 1.30 began to vomit, and continued at intervals, with profuse sweating, till 3 P.M. Found her languid, with pulse 42, without pain. Gave a small opiate, after which there was no more vomiting. 3.45, pulse has been at times as high as 48; now 42, of fair strength and fullness; respiration 10; three inspirations followed by a long rest. She lies quietly, with eyes shut, disinclined to speak; pale; feet and legs still oedematous; brandy 5 ij. Patient went on favorably; urine passed freely, and oedema subsided in the course of a week.

There are three points worthy of notice in this treatment of puerperal convulsions; 1st, the relief is permanent, in which respect the method differs from all others; 2d, the relief comes when the pulse is reduced much below the normal standard, with free perspiration, vomiting, and general relaxation; 3d, this depressed condition is not dangerous nor alarming, but passes off in a few hours.

CASE VII. By DR. A. L. LOWELL.—Mrs. S. G., aged 24, of good antecedent history, primipara, fell in labor at full term at midnight on the 23d April, 1873. During gestation there had been oedema of face, hands,

and lower limbs; occasional scanty urination. Symptoms supposed to have been referable to albuminuria of gestation; face and neck of a waxy pallor, urine albuminous, about two-fifths its volume, at first visit, at 9 A.M., April 24th; casts in large number, chiefly fatty and granular. Labor: first stage ended at 4.15 P.M.; second stage at 6.35; and the third at 7 P.M.; delivered of a living male, weighing five pounds, which survived three months. At 7.35 had a well-marked eclamptic seizure; pulse, 100, full and hard; followed by stertorous coma. Decided to employ veratrum solely; gave 20 drops of the fluid extract (Squibb's). Repeated the dose at 8; pulse less tense. At 8.30, gave 20 drops more; pulse 80; skin, hitherto dry and hot, slightly moist. At 9, 20 drops more; pulse 72, with diminished tension; slight nausea; patient can be partially roused. At 10, 20 drops more; pulse 60, profuse perspiration. At 10.20 the last dose was given, twelve drops, producing decided nausea and bringing the pulse down to 54 beats per minute. Patient presently fell asleep, and passed a quiet night. No more convulsions. Recovery prompt, although urine was albuminous for over two months, and casts were found six months later.

CASE VIII. By DR. E. S. BUNKER.—The fluid extract of veratrum viride given hypodermically in large doses. Sarah D., aged 19, unmarried, a domestic, was seen August 22d, 1873, in consultation with Dr. D. Ambrose. Pregnant condition had been concealed from the family for whom she worked by tight-lacing; had had severe headache, face and ankles puffy, great drowsiness at times.

At 8 A.M., while at work, fell suddenly in a convulsion, which recurred during the day, at the rate of three or four each hour. No urination, vomited frequently. Saw the patient at 3 P.M.; found labor-pains rapid and powerful, each accompanied by a furious convulsion. In the interval she was unconscious, almost comatose; pupils dilated and insensitive.

General anasarca present; bladder empty. Delivery was soon accomplished, by forceps, under chloroform. Child large and living.

Convulsions continued, followed by profound coma; pulse rapid and feeble, temperature 103°. A little urine was drawn, highly albuminous. At 10 P.M., ten drops of the fluid extract of veratrum viride were given by the mouth; pulse 100. More convulsions. At 11, ten drops more. At 11.45, a "frightful" convulsion took place, and death seemed imminent. Deglutition being impossible, the subcutaneous method was resorted to; keeping the needle in place, two minims were injected at intervals of about one minute. The pulse was closely watched, and finding the medicine well borne, the dose was increased to five minims, then to ten, and ultimately to fifteen minims. The pulse gradually fell, and skin became moist. At 2.10 A.M. (Aug. 23), there have been two more convulsions; pulse 100, temperature 103.5°. Twenty minims injected, a total of 320 minims. At 6.15 there have been five more convulsions; a thirty-minim injection given, the second of that quantity, total minims 425; pulse 120. The latter has been as low as 96 in the intervals. Bowels moved by turpentine enema. The first thirty-minim injection, at 6 o'clock, was followed suddenly by the discharge of a large quantity of urine, which saturated the bedding and ran over the floor. At 9.25 there has been no recurrence of convulsions; pulse 96. At 1 P.M., pulse 112; temperature 101°; skin moist, urine abundant. Acceleration of pulse is met by occasional ten-minim injections. At 7 P.M., the last was given, the total amount of the fluid extract of veratrum viride administered in 19 hours being 500 min-

ims. Free catharsis, induced by compound jalap powder at midnight; lochia, good; diet, meat-juice and milk. Aug. 24 (third day). Patient lies in a quiet, bewildered state; pulse about 108; temperature 101°. Aug. 25 (fourth day). Patient wakeful and partially restored to consciousness; pulse, 100. Sept. 1. Has nursed infant during five days; this afternoon went home with the baby in her arms.

Summary.—The period of six hours, ending 6.15 a.m. (Aug. 23), after which no convulsions recurred), may be divided into four smaller periods of one hour and a half each. In the first period, 285 minims were exhibited; in the second, 35; in the third, 15; and in the fourth, 90 minims. The results of the large dosings of the first period appear in the fact that there was only one convulsion in that time; and their effects continued through the second and third, one convulsion in each. And then the quantity, 50 minims, proving inadequate, a relapse occurred in the fourth period, with four convulsions. Large doses were promptly injected, and here the trouble and peril ended. No serious irritation arose from the tattooing of the arm by the hypodermic needle. The patient is alive and well.

Dr. S. SHERWELL stated that Nov. 25, 1872, he used the fluid extract of veratrum hypodermically, three minim doses in the treatment of puerperal convulsions; also in apoplexy and stroke.

REMARKS ON THE VERATRUM TREATMENT OF PUERPERAL ECLAMPSIA.

Dr. E. R. SQUIBB. The cases of puerperal convulsions treated by veratrum that have been reported here proved to his mind that, first, there is no fixed dose—the test must be the effect produced, and not the number of minims given. The tendency in therapeutics, at present, seems to be to get rid of the trammel of dose, and neither uphold nor condemn a remedy because a given quantity does not produce an invariable effect. Idiosyncrasies are to be intelligently studied in the administration of veratrum, just as they are in other therapeutical measures. Again, the drug is shown by these cases to be eliminated with great rapidity. In one of Dr. Fearn's cases the omission of a dose was attended with an immediate rise of the pulse. The same is true of the narcotics. Thirdly, there is an intensity of habit in convulsions; they tend to recur until the habit is broken by a profound sedation of the heart's action. The dose can then be reduced. There is no great danger from the drug so long as the convulsive tendency remains. He recalled to mind the instructions of Dr. Meigs as to the treatment of eclampsia. Dr. M. was accustomed to say that when a puerperal woman complained of severe frontal headache, and cried out, "O doctor, I can't see!" his impulse was to bleed. Sometimes he resisted this impulse; and when he did, he was sure to be sorry for it afterwards; for it was exactly in those cases that convulsions occurred. The bleeding prevented their occurrence; but, having begun, the bleeding would not subdue them. Let veratrum in like manner be used as a means of prevention.

The physician must discriminate between his cases. In a late issue of a Philadelphia journal a number of cases are reported where veratrum did harm; the drug is therein thoroughly condemned. He inclined to the belief that the drug does good only where the sthenic condition or type exists, as is commonly the case in young primiparae. In the asthenic, when the pulse is rapid, but weak, it will prove injurious. The fact that primiparae form so large a proportion of the subjects of eclampsia, may explain the freedom with which veratrum has been safely and happily given in

so many cases. Something yet remains to be learned of the disease, before we can harmonize the reports of those who condemn the drug as thoroughly as others have lauded it. The question has been asked, What dose should be given, and what rules govern us as to its exhibition? There is no dose that will suit all cases. Effects should be watched for with the finger on the pulse. Anywhere from fifteen drops upwards of the tincture may be given until the irritability of the nervous system, on which the convulsions depend, is subdued. Anything short of this will be of only temporary utility, for the medicine is very rapidly eliminated from the system, and the effects of the medicine soon disappear; so that if large doses are not given, the dose must be repeated very often to maintain its control over the circulation. Therefore the pulse must be watched constantly. For rules of exhibition, see my paper in *Obstet. Journal (American)* for May, 1871.

The quantity required depends on the character of the case. In peritonitis, and also in flatulent colic, morphine is a very valuable medicine. But while none would think of giving six or more grains of morphine in a day in any ordinary case of the latter, few would hesitate to give that quantity, or more, in a severe case of peritonitis. The intensity of the morbid action is such as to resist the ordinary powers of the medicine in small doses.

Dr. C. H. GIBBERSON. He, with others, had been somewhat startled by the original propositions made by Dr. Fearn in his paper read before this Society in 1869. Since that time, however, he had made an examination of the literature of veratrum viride, and he now believed that the extreme dread of the remedy, which had led to its disuse, was not warranted by the recorded facts. We have been taught to overrate its danger. There are other remedies in daily use which have a far more fatal record. Since Dr. Fearn's paper was presented, Dr. G. has had but one case of puerperal convulsions, and now regrets that he had not treated the case with veratrum. From his present knowledge of the subject, he believes that the case was exactly of the kind which may be saved by its use. Labor was ushered in by a convulsion, tetanic, and almost continuous, delivery was induced under chloroform; inhalation of the latter was continued during the greater part of ten hours. Patient died very soon after delivery. At the present time he is interested in a case of threatened uremia in a primipara, having frontal headache, general anasarca, and urine albuminous, but not of very low specific gravity. Will the veratrum treatment apply to such cases for the prevention of convulsions before the labor-term has arrived? He hoped that an extended circulation might be given to the experience of our physicians in the treatment of puerperal convulsions by large doses of veratrum. The "Brooklyn treatment" has been the source of some amusement to several of the profession; possibly it may become the occasion of a gratification of another sort—possibly the life of some patient may be saved by it.

Dr. J. H. H. BURGE. In the early years of his practice he had had six cases of puerperal eclampsia, and all had recovered without veratrum. He feared that heroic doses of it might have done harm to some of those cases.

Dr. A. OTTERSON. No one will doubt that we have a powerful agent in veratrum viride, but it is not so clear that it is a safe one. He believes it is sometimes potent beyond anticipation, and gets beyond the control of the physician. About twelve years ago it was prominently brought before the profession by Norwood, and

some other Southern practitioners, and was used by himself in a number of cases of acute and inflammatory disease, and in 1861 he wrote an article, commending the trial of Norwood's tincture, for *The Medical Monthly Review*, which was reprinted by Braithwaite, January, 1862. It never became very popular in this section, and he had happened to see so many cases of extreme prostration that he had for some time used it with great circumspection. He related one case of a robust ship-carpenter, sick of pneumonia, treated by a Thompsonian by large doses of veratrum viride, who was so thoroughly prostrated by the drug that he was supposed to be in a dying condition for several hours. When the speaker was called to see the patient he was insensible, voiceless, and almost pulseless. Stimulants, carbonate of ammonia, and the galvanic current were used for his relief, but without apparent results. Subsequently, however, the sedation passed off and the man recovered.

It may well be doubted if the mere sedation of the heart's action produced by veratrum viride will cure all cases of puerperal convulsions. He knew of a case of that kind, in which the pulse was less than 50 per minute, and yet the convulsions recurred. Six drachms of Norwood's tincture were given to this patient in 18 hours, the physician visiting the patient nine times in that period of time. Patient recovered.

Dr. S. G. ARMOR has had no experience with veratrum in convulsions, but had used it freely twenty or more years ago, when living in the West, where its merits have been pretty thoroughly canvassed. Dr. Norwood visited him in Cincinnati, and had with him tested the agent in the wards of the hospital with which he was then connected. Dr. N. vaunted the remedy in every condition in which the pulse was accelerated, whether in typhoid or sthenic types. His own views are that it is solely a cardiac sedative, and all its good effects come from the property it has of depressing the sympathetic system. The temptation is to give too great significance to the heart's action, and to consider that having reduced its excited action the disease has been abated. This does not follow: the heart may beat rapidly as an effort of nature to adjust or render normal some underlying diseased condition. When the proper class of cases for cardiac depressants shall have been found, the proper treatment will probably be by the joint action of aconite and veratrum; the combination will find a wider range of sedative action than either drug alone. Dr. Fearn, who deserves to be immortalized in the literature of this subject, may have discovered one of the valuable uses of depressants. For the present, his own experience and his knowledge that in the western and south-western sections of this country, where the virtues of veratrum have been thoroughly tested, it has lost ground, in addition to his therapeutic theories, lead him to believe that the curative properties of the drug, as applied to inflammatory disease, have been overestimated, and that its supposed curative action has been explained and based upon a line of fallacious reasoning.

Dr. C. H. GIBERSON. As to the use of veratrum in catarrhal and chest affections, he could not discover that it had any advantage over aconite, which has been largely used at home and abroad of late.

Dr. N. FORD. While in the country, some years ago, on a health trip, he saw veratrum used very freely and frequently by a country practitioner—his own uncle. On one occasion so very profound prostration was produced by it that death appeared imminent; the stimulants were poured into the patient, and on the second day he rallied. For himself, he was thoroughly alarmed at its effects. His uncle, however, was full of confi-

dence in the remedy, and used it in nearly all inflammatory affections, regarding it as especially efficacious in diphtheria. Certainly the results of this treatment were more encouraging than those of other physicians in his neighborhood. His habit was to give 3 ss. doses of the tincture every twenty minutes, so as to keep the pulse under the normal standard. He remained as much of the time as possible with his patient, and when called away directed the manner of stimulation to be employed if prostration should supervene. For himself, Dr. Ford could not adduce any experience in the use of such heroic medication.

Dr. J. T. CONKLING. He now uses veratrum viride almost daily in cases where he formerly used aconite; he carries a bottle of the fluid extract in his pocket. The acute symptoms of rheumatic fever, especially in young subjects, are greatly relieved by it. He gives two-drop doses every two hours. When some nausea is produced the effects of the remedy seem especially satisfactory.

Dr. B. F. FESSENDEN has lately treated two cases of hysterical convulsions with ten-drop doses of the fluid extract every two hours; prompt relief was afforded.

ON THE ADMINISTRATION OF VERATRUM VIRIDE.

Dr. E. R. SQUIBB, in reply to a question concerning the strength of the fluid extract made by him, stated that it is twice as strong as Norwood's tincture. The latter is often spoken of as a saturated tincture, but it is not that. The tincture necessarily varies greatly because of the imperfect description of its preparation; the different parts of the plants, the different methods of drying it, the different seasons of collecting, and some other causes, have tended to make Norwood's tincture a most uncertain article. These various avenues of error have lately been closed by the exact methods of preparing the official extract. Of the alkaloids, veratria and veratroidia, the latter was supposed to be the cardiac sedative, and the former the irritant and emetic; their superiority to the fluid extract has not been demonstrated. The extract is the safer, since the drug is very susceptible to change under chemical manipulation. The tincture, and the extract as well, are permanent preparations. Dr. Fisher, of Sing Sing, N. Y., who in 1854 or '56 began the use of a certain package of the extract, and continued to use the same until lately, reports that the last drop seemed to be as potent as the first.

Two points in the administration of remedies should ever be borne in mind. First: the stomach under certain conditions is impassive—cannot absorb its contents: this is frequently the case in the obstetric administration of ergot; it might as well be put in a bag; double-dosing and unexpected results may in this way be brought about. Second: there must be used a proper vehicle, or menstruum, and an accurate measure. The fluid extract of veratrum, like the other extracts, is precipitable in water, and if given directly may collect on the teeth and gums. The country practitioner who, for the reason that he must do his own dispensing, studies the matter closely, and hits upon the most precise methods, commonly prescribes the extracts by measuring into a glass a number of teaspoonfuls equal to the number of doses to be given, and then adds the appropriate amount of the drug, directing that the medicine be stirred before being given.

Dr. H. FEARN has commonly adopted the plan of dropping the extract upon sugar before adding water to it.

Dr. B. A. SEIGR adverted to some experiments

made by him to test the advisability of administering fluid extracts by the drop. He found that the size of the drop varies from 2 to 4 drops to the minim, according to the shape of the vehicle from which it is dropped. So great was the disparity, that he had concluded no longer to prescribe by the drop.

Correspondence.

RELATIVE vs. POSITIVE RANK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—As the rank of the Medical Staff of the Army is at present claiming the attention of the profession, permit me to make a few remarks upon a paragraph contained in an editorial in THE MEDICAL RECORD of the 15th December, 1873. In speaking of the action of the American Medical Association, you say:

"It will also be recollected that resolutions were passed expressing the opinion that the rank of the Medical Staff of the Army should be equal to the *relative rank* held by the same corps in the navy." etc. The italics are mine, for I desire to call special attention to the words *relative rank*, which in reality is no rank at all, as it has not and never can have a particle of value in the estimation of military or naval men. What is needed for the medical officers of both services is a positive or *bona fide* rank, unqualified by the terms relative or assimilated, or by any word which may in the slightest degree detract from its military value. Now in the navy, if a staff officer has the temerity to speak of his rank, he is immediately reminded that it is "merely *relative*," and he may be asked, with a shrug of the shoulders, to show any authority for rank in his commission. This is a crucial test; for the crestfallen staff-officer is aware that the word *relative* has not even a place in that document, and it is useless for him to appeal to Mr. Stevens's speech, or to refer to the Act of March 3d, for there is no getting over the fact that his commission does not say one word about rank in the sense in which that term is understood in the military world. The time has now arrived for a definite understanding about this matter; and medical officers should petition Congress for a *positive* status, avoiding carefully any phraseology which may imply an inferiority of position. Until this end be attained, and until every surgeon's commission shall show upon its face that he has been appointed a *surgeon with the rank of* (not with the assimilated or relative rank of) major, no amount of argument will convince his military conferees, or the public, that he is possessed of any legitimate rank whatever. With regard to military or naval titles, I believe that the majority of medical officers are opposed to their use, but it seems likely that eventually they will be obliged to adopt them, in order to enforce or exact that deference and obedience which soldiers and sailors are not willing to show to surgeons as surgeons, but which they are obliged to pay to their military grades of major or colonel. In a recent conversation with the medical officers of the Royal Victoria Hospital at Netley, upon this very subject, I found that English army surgeons were now alive to the necessity of substantive rank, *with a military title*, as in the case of paymasters and judge-advocate in our army, for they are evidently disheartened by the late "Order in Council" which has changed the title of Inspector-General to that of Surgeon-General, and otherwise diminished their status and military privileges.

If any proof be needed of the absurdity of *relative* rank, as it now exists in the navy, I would refer your readers to the "Regulations" of that branch of the service, in every page of which may be found some pitiful deduction from the rank of the staff. True, these officers are accorded precedence in court-martials and at funerals, etc., but they have often to fight for it; and if they are not fortunate enough to have a copy of the Act of March 3d in their pockets, they will probably find themselves out of place on many occasions. Civilians, of course, are not posted about the relations between professional and military grades, and military men are *indifferent* to them, consequently awkward mistakes occur; for it is not likely that a staff officer will rush up to his host or his commanding officer with a copy of the "Blue Book" in one hand and an Act of Congress in the other, in order to convince him of the necessity of his having a particular place or station. Again, we find the strange inconsistency which refuses military honors, salutes, etc., to staff officers, while it gives them to Supreme Court justices, consuls, and the civil members of the government. Why is this distinction made? Why, Mr. Editor, is a commodore in the line, or a *chargé d'affaires*, received with a salute of thirteen guns, while a commodore on the staff and the head of a government bureau is refused the same mark of respect?

Even after death these invidious distinctions are made. Minute-guns are fired at the funeral of a line officer, but powder is too valuable to be wasted over the carcass of a staff officer of *relative rank*. And so I might go on *ad infinitum*, enumerating these petty and contemptible efforts to belittle and degrade the relative rank of the staff. I must not, however, trespass further on your good-nature; but, in conclusion, I would again call attention to the evil entailed upon the navy by the use of the word *relative*, and to the absolute necessity for officers of both services to hold a *bona fide* rank which shall carry with it *all* the honors, privileges, and immunities of the line.

I am your obedient servant,

A NAVAL SURGEON.

CARBOLIC ACID IN TAPEWORM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In a recent issue of your valuable journal I noticed a letter from Dr. Bill, of the army, recommending the use of carbolie acid in the treatment of tapeworm.

Having a case on hand at the time, which had resisted the use of oil of turpentine and bepo for a month or six weeks, I immediately administered to him the following prescription: R. Acid. carbolie cryst., gr. ij.; glycy. pulv., gr. iv. Ft. pil. No. 2. To be taken every three hours, beginning at 9 A.M. and continued until 9 P.M. This, followed in the morning by jalap and rhubarb, ten grains each. On the first day a few joints were passed, on the second a great number, and on the third the head and narrow portion came away, with a great number of small sections from one to three inches long. On the fourth day, treatment being kept up without further result, the medicine was discontinued.

The only sensation created in the stomach by the administration of such large quantities of the drug was a slight burning, not sufficient to inconvenience the patient. I look upon this as a perfect cure, and therefore report the case to you.

Very truly yours,

S. AUSTINE BROWN, M.D., U. S. N.

U. S. S. KANSAS, KEY WEST, Feb. 5, 1874.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 19, 1874, to March 4, 1874.

BAILEY, E. J., Surgeon.—To report in person to the Commanding General Dept. of California for assignment to duty. S. O. 45, A. G. O., March 2, '74.

WILSON, ALFRED D., Asst. Surgeon.—Granted leave of absence, on Surgeon's Certificate of Disability, for 60 days. S. O. 47, Mil. Division of the Atlantic, March 3, 1874.

SIMPSON, JOSIAH, Surgeon.—Died at Baltimore, Md., March 3, 1874.

Medical Items and News.

THE LUNACY LAWS.—The bill of Mr. Prince, in regard to the safe-keeping of lunatics, passed the Assembly by the vote of 81 to 9. The following is the bill in its amended shape: The Governor of the State is authorized to appoint for the City and County of New York not less than ten nor more than fifty, and in every other county not less than five nor more than fifteen, respectable physicians, to be known as Examiners of Lunacy, and to fill vacancies occurring among such examiners as they occur; and in every case arising in any county requiring, as now provided by law, the certificate of two physicians to require the confinement for safe-keeping of any person on the ground of lunacy, such certificate shall be required to be signed by two of the Examiners of Lunacy so appointed, resident in the county in which such case of lunacy is found; and no person shall be received as a lunatic in any asylum, public or private, without such certificate. The appointment of examiners, as aforesaid, shall be made on the recommendation of the Boards of Supervisors, or a majority of the members thereof, of the respective counties. Said examiners shall hold office during the pleasure of the Governor, and vacancies shall be filled in the same way in which the original appointments are made.

SURGEON JOSIAH SIMPSON, U. S. Army, died in Baltimore, Md., March 3, aged 59 years.

THE SIAMESE TWINS.—A further autopsical examination of the twins has verified the suspicion that the tract of "portal continuity" is really liver-tissue—a fact which would have seriously militated against the operation of a separation of the two bodies.

EXTENSION BY ADHESIVE PLASTER.—ITS FIRST EMPLOYMENT.—Dr. L. Mosely, President of the Bennington Co. (N. H.) Medical Society, in his annual address recently delivered before that body, gives quite an interesting account of his first use of adhesive plaster in the treatment of fracture. He says that in 1840, having a bad case of fracture of the thigh, in which the appliances, then in use, not being sufficient to make and maintain extension, he conceived the idea of spreading two strips of bandage, with adhesive plaster, applying the same on either side of the leg, tying the ends together, and making a loop under the foot, from which to make the extension. He was enabled to carry out his idea very effectually and successfully. Dr. Gregg, a relative of Dr. Mosely, on a visit to the latter, having seen this case, returned home soon after and put the idea in practice. Dr. Mosely continued the plan of extension in the treatment of every subsequent case, and believed it original. While

on a visit to the New York Hospital in 1852 he was, however, surprised to find this method of extension in use in that institution. Mentioning the fact to Dr. Gregg, that gentleman informed him that he (Gregg) had showed a case under treatment to Dr. Crosby, who thought the idea a good one and adopted it in toto, subsequently reading a paper upon it before the New Hampshire State Medical Society. Since that time it has been known as "Crosby's method." Dr. Mosely proves himself to have made a very unfortunate mistake in not publishing his discovery at once, for as the matter now stands it is too late to lay any claim to the invention in question.

THE LATE DR. ROBERT I. GRAVES.—A number of the former pupils, friends, and admirers of the late Dr. Robert I. Graves, residing in different parts of the kingdom, have agreed to form a committee for the purpose of receiving subscriptions for a statue, which, in accordance with a resolution of the College of Physicians, is to be placed in the hall of the College.

It is to be hoped that the committee will receive cordial co-operation and support in the endeavor to raise so well deserved a memorial to this distinguished representative of the Irish school of medicine.

The committee is composed of William Stokes, A. Hudson, W. E. Wilde, Hon. Secretaries.

DEATH OF FORBES WINSLOW, M.D.—A telegram of the 4th instant announces the death of Dr. Winslow. This eminent physician and author was the son of a British officer, and was born at London in 1810. He began his professional studies in this city, and continued them on his return to London. In 1835 he became a member of the Royal College of Surgeons, London, and soon afterwards received his diploma as medical doctor at King's College, Aberdeen. He was also, about the same time, elected a Fellow of the Royal College of Physicians at Edinburgh. Dr. Winslow's love for metaphysical and philosophical reading led him almost instinctively to the investigation of mental diseases, and he became eventually the leading authority in England on all questions relating thereto. During some part of his early life he was on the literary staff of *The London Times*, and was also an industrious writer of books on medical topics, having produced before his thirty-fifth year two manuals, a "Medical Sketch-book," and an interesting work called "The Anatomy of Suicide." He afterward wrote several volumes relative to the responsibility of insane criminals, the management of lunatic asylums, and kindred subjects. His best known work, on "Obscure Diseases of the Brain," first published in 1860, has gone through four editions in London, and three in this country. *The London Lancet* considered it "the future text-book on mental and cerebral pathology," and another medical authority pronounced it "the master-effort of a great philosopher." Dr. Winslow founded, in 1848, *The Quarterly Journal of Psychological Medicine*, which he conducted for sixteen years. About 1847 he established Sussex House, Hammersmith, a private asylum for the insane, and for many years gave that institution his personal supervision. He had a large private practice in cases of insanity and diseases of the nervous system. He was also frequently consulted as a medical referee in cases of alleged insanity in the courts, great weight being accorded to his opinions.—*Tribune*, March 5th.

MEDICATED CANDLES.—An English manufacturing firm have introduced, for medical purposes, candles medicated with the balsams of which the vapor is most often beneficially inhaled by persons suffering from bronchial irritation and spasmodic asthma. Among these are benzoin, storax, etc.

THE WATER-SUPPLY of several cities, as calculated for each inhabitant, is as follows: Lisbon, 18 litres per diem; Montpellier and Nantes, 60; Brussels, 80; Paris, 100, soon to be 200 or 300; Madrid, 119; London, 130; Bordeaux, 170; Marseilles, 500; and in New York, 508.

Dr. H. KNAPP has been appointed consulting oculist for the several institutions of the Department of Charities and Correction.

THE AMERICAN MICROSCOPICAL SOCIETY has elected the following officers: John B. Rich, M.D., President; O. G. Mason, Wm. H. Atkinson, M.D., and John Frey, Vice-Presidents; D. H. Goodwillie, M.D., Corresponding Secretary; J. P. Wintringham, Recording Secretary; Prof. T. d'Oremieulx, Treasurer; Samuel Jackson, Curator; S. G. Perry, Librarian.

BELLEVUE HOSPITAL MEDICAL COLLEGE.—The thirtieth annual commencement of this college was held at Steinway Hall, on the evening of Feb. 26, in the presence of a crowded audience. Music was furnished by the Twenty-second Regiment band, under the direction of P. S. Gilmore. Following a prayer by the Rev. Alfred B. Beach, D.D., chaplain of the college, and the conferring of degrees by Professor Isaac E. Taylor, M.D., the President of the Faculty, addresses were made by the Rev. J. M. Gallaher, and Smith E. Winn, of Kentucky, of the graduating class.

The first Taylor prize, of \$100, to the one passing the best examination, was awarded to Frederick S. Dennis, of Newark, N. J., and the second Taylor prize, of \$50, to David C. Cocks, of New York. Of the two Wood prizes, for the best preparations relating to surgical anatomy, only the second, of \$25, was awarded. This was given to Mr. W. J. Alexander, of Mississippi, an under-graduate.

After the exercises at Steinway Hall the graduates, together with distinguished guests, were entertained by the Faculty of the College with an elegant supper at Delmonico's, at Fourteenth street and Fifth avenue.

After justice had been done to the dishes, President Taylor made a few remarks, referring to the significance of the occasion, to the severance of the ties which had been formed, by this farewell of graduation, and to the formation of a new and stronger union with those graduates to whom the reputation and prosperity of the college are now committed. He closed with the sentiment, "Our guests, the recent graduates of the Medical College of Bellevue Hospital—may health, happiness, and prosperity attend them." Henry Flood, of the graduating class, replied, enlarging upon the merits of the college, and asserting the claims of New York for recognition as the centre of medical instruction for the country.

President Taylor then called upon the "Nestor of Bellevue," Dr. James R. Wood, who recounted the early history of the hospital and of the college, and detailed the difficulties which he had found in extending the great principle of combining clinical with didactic teaching, whose glorious fruition he now looked upon.

Commissioner Henry Laimbeer was the next speaker. He set forth the importance of the voluntary medical assistance in the relief of the destitute suffering extended to the Board, and declared the greatness of the work done by the medical profession in the city, and the excellence of her medical colleges. Commissioner Meyer Stern was then called upon. He argued against giving the responsibility of appointing medical officers in the institutions and hospitals to the Commission of Charities and Correction, believing that professional men, better able to judge of the qualifications required, should do that work.

Sentiments and responses then quickly followed in the following order:

The health of Ex-Commissioner Jas. B. Nicholson, Esq., one of the oldest and truest friends of the college.

"Our Trustees,"—Ever ready to clear the horizon and give us an uninterrupted *belle-vue*, to which Rev. Dr. Rogers responded.

The health of Geo. F. Talman, Esq., President of the Board of Trustees.

"Medical Ethics," responded to by Prof. A. B. Crosby.

"Universal Orthopedy—educating straight crooked feet, crooked ethics, and crooked morals," responded to by Prof. Lewis A. Sayre.

"The two Doctors—one for the body, one for the soul," responded to by Rev. J. N. Gallaher, D.D.

"Our reverend Chaplain, beneath whose beneficent influence we recline like Tityrus." "*Subtegmine fagi*," responded to by Rev. Alfred B. Beach, D.D.

"Woman—without whom we are not; with whom we are not much," Prof. B. Fordyce Barker.

The class of 74. Thos. C. Hennessy, of the Class.

COLLEGE OF PHYSICIANS AND SURGEONS, N. Y.—The Commencement Exercises of the College of Physicians and Surgeons took place at Steinway Hall, on the evening of March 3d. Among others present were Thurlow Weed, the Rev. Dr. McCosh, Prof. Chandler, the Rev. Dr. Storrs, Dr. Van Buren, Col. F. A. Conkling, Prof. Clarke, Prof. W. Parker, Prof. Dalton, Dr. J. Poole Garrish, Prof. St. John, and Prof. Jacobi. After various musical selections the degrees were conferred by Dr. E. D. Beadle upon the graduates.

The first graduating Faculty prize was awarded to Henry J. Hineman for the best thesis on "Naso-pharyngeal Polypus." The second graduating prize was awarded to Chas. H. Langdon for a thesis on "Aphasia." The Alumni Association prize of \$200 was awarded to A. H. Buck, M.D., for a thesis on the "Mechanism of Hearing." The Thomas prize was awarded to J. E. Stillwell, for a report on "Clinique for Diseases of Women." The Otis prizes were awarded to Fred. A. Lyons and E. B. Foote, Jr., for the best report on "Venereal Lectures and Clinique." The Seguin prize was awarded to W. H. Welch for the best report on "Clinique for Nervous Disorders." A prize to be awarded annually after next year will be known as the Smith prize, and will consist of \$100. In 1875 it will be given for the best report on "Hygiene in either of its Special Departments."

After the prizes had been awarded the valedictory address was delivered by Porter Farley, A.B., M.D. The Rev. Dr. Storrs then addressed the graduating class.

THE ANNUAL DINNER OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS took place on Monday evening, March 2d, at Delmonico's. The table was spread for about 150 guests. Among those seated on the platform were the Hon. John R. Brady, the Rev. Dr. McCosh, Dr. Willard Parker, Prof. H. Drisler, the Rev. Dr. Montgomery, and many others. Dr. Charles M. Allin, President of the Association, occupied the chair. After partaking of a sumptuous repast, the cloth was removed and the following toasts were given and responded to: "Columbia College," responded to by Prof. H. Drisler; "Our Alma Mater," a fostering mother of the science and art of medicine, by Dr. Willard Parker; "The True Place of Money, Endowments in Institutions of Learn-

ing," Rev. Dr. James McCosh, of Princeton; "Sister Colleges"—may their only rivalry consist in striving to make the most complete and thorough provision for scientific study, Prof. Chas. E. Buckingham, of Harvard; Prof. Francis Bacon, of Yale; Prof. A. B. Crosby, of Bellevue, and Prof. W. H. Thomson, of the University Medical Department. Letters also were read from Professors Pepper, and Horatio C. Wood, Jr., of Philadelphia. "The Clergy"—fellow-workers with the physician in alleviating human woes, Rev. Dr. H. E. Montgomery; "The Lawyer and the Doctor"—frequently associated in the same field, our mutual interests demand a more intimate relationship, Judge Jas. R. Brady; "The Press"—the great remedial agent for torpidity of the public liver, and biliousness of the body politic, J. M. Bailey, Esq., of *The Danbury News*; "The Medical Staff of the Army and Navy"—our profession has but one voice, and that in favor of their rank being commensurate with their education and services, Dr. Edw. Curtis, late of the U. S. Army; "Our Fellow Alumni Associations"—one in purpose, though different in organization, Prof. J. R. Leaming, of the University, and Prof. W. T. Lusk, of Bellevue.

THE THIRTY-THIRD ANNUAL COMMENCEMENT OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY took place at Steinway Hall on the evening of February 17th ult., Chancellor Howard Crosby, D.D., presiding. Grafula's orchestra furnished excellent music for the occasion, and following the reading of the twenty-fifth chapter of Matthew and a prayer, the list of graduates was read.

The diplomas were then awarded, and the following gentlemen, mentioned as having particularly distinguished themselves in their examinations, had certificates of honor awarded them:

Barbarossa, Bentley, Bentz, Brown, Carreau, Denhard, Desvernine, Doherty, Gutierrez, Hanford, Hill, Jimenez, Kissam, McAuley, McCormack, McLoehlin, Martin, Morrogh, Piercy, Pinto, Pray, Ransom, Spillane, and Wilbur.

The first prize, by Prof. Budd, a case of obstetrical instruments, was awarded to C. F. Ainsworth, who also received Prof. Loonis's prize, another case of instruments. Prof. Thomson's prize was won by J. S. Carreau. The prize of Prof. Roosa, a case of instruments for the eye and ear, was gained by H. F. Kingsley. Prof. Arnold's prize of a microscope was awarded to L. Gutierrez, who also took the prize of \$50, offered by J. Boyce. The prize offered by Prof. Elsberg, \$50, was given to P. J. Keegan. Besides these there were the three "Mott Medals." The gold one was won by John Wilbur, the silver by G. A. Balcom, and the bronze by S. B. Young.

Mr. Whitelaw Reid then made some exceedingly pertinent remarks, and was followed by Prof. Budd, who delivered the valedictory.

THE ANNUAL MEETING OF THE ALUMNI ASSOCIATION of the Medical Department of the University of the City of New York was held Feb. 6th, at which the following officers were elected for the coming year:

President: James R. Leaming, class of '49. *Vice-Presidents:* A. L. Carroll, class of '55; Wm. Canniff, class of '54; S. Fleet Speir, class of '60; Bolling A. Pope, class of '56; Thos. C. Finnell, class of '49; J. H. Hobart Burge, class of '48. *Secretary:* Charles Inslee Pardee, class of '60. *Treasurer:* D. B. St. John Roosa, class of '60. *Executive Committee:* James H. Anderson, class of '60; Joseph S. Monell, class of '61; S. Seabury Jones, class of '69; C. Dixon Varley, class of '44; Harvey S. Gay, class of '49; Joseph W.

Howe, class of '66; Stephen J. Clark, class of '61; F. R. S. Drake, class of '71; F. Le Roy Satterlee, class of '68; A. E. McDonald, class of '70; Joseph J. Hull, class of '58; and John W. Hunt, class of '59.

AT A MEETING OF THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, held Wednesday evening, Feb. 25, the following officers were elected for the ensuing year:

President: C. M. Allin. *Vice-President:* Alfred S. Purdy. *Secretary:* George Bayles. *Treasurer:* [not yet appointed]. *Councillors:* C. R. Agnew, C. M. Allin, A. Brayton Ball, J. S. Banks, Robert A. Barry, George Bayles, John N. Beekman, D. Tilden Brown, Albert H. Buck, Gordon Buck, H. W. Buel, F. A. Burrall, T. M. Cheesman, J. W. G. Clements, Francis Delafield, Stephen Dodge, Alexander M. Docherty, W. H. Draper, Abraham Du Bois, Ellsworth Eliot, William S. Ely, Henry C. Eno, Porter Farley, Frank P. Foster, John Shrady, A. H. Smith, G. M. Smith, T. Blanche Smith, Benjamin Swan, Edw. H. Van Deusen, Henry F. Walker, Robert Watts, George G. Wheelock, Robt. F. Weir. *Trustees:* Robert A. Barry, D. Tilden Brown, H. C. Eno, T. H. Satterthwaite, C. R. Agnew. *Executive Committee:* A. H. Smith, George A. Peters, W. H. Draper, Robert F. Weir, Albert H. Buck, T. Matlack Cheesman.

The Alumni Prize of \$200 was awarded by the Committee to Albert H. Buck, for his paper on "The Mechanism of Hearing." A similar prize is offered for the best essay to be submitted at the meeting of 1875.

The Treasurer reported that there are between \$3,500 and \$3,600 belonging to the "Alumni Prize Essay Fund," which is drawing interest, and that about \$55 had been subscribed during the past year. "The General Alumni Fund" amounts to \$4,753, and the "Joseph Mather Smith Fund" to about \$1,500.

It was reported that by the recent action of the Faculty of the College of Physicians and Surgeons, the President of the Alumni Association is entitled to a seat in the Board of Trustees of the College.

THE ANNUAL MEETING OF THE ALUMNI ASSOCIATION OF THE BELLEVUE HOSPITAL MEDICAL COLLEGE was held at the College, Monday evening, March 9th, and the following officers elected for the ensuing year: *President,* T. R. Pooley; *1st Vice-President,* J. D. Bryant; *2d Vice-President,* Robert Newman; *Recording Secretary,* George W. Wells; *Corresponding Secretary,* C. A. Neale; *Treasurer,* Henry Raphael; *Historian,* F. A. Castle.

ALUMNI DINNER.—The third annual dinner of the Alumni of the Medical Department of the University of the City of New York took place at Delmonico's on the evening of the 16th ult. Shortly after 6 o'clock about fifty guests sat down before a superb bill of fare, and proceeded to discuss the edibles with a commendable gusto. Prof. Jas. R. Leaming presided. After enjoying the material elements of the menu the company listened with evident gratification to the following toasts, and the responses made thereto by the gentlemen indicated:

The University.—Her training such that she may furnish and instruct great teachers, and never seek for aid out of herself. Rev. Howard Crosby, D.D., Chancellor; Wm. R. Martin, Esq.

The Medical Department.—A vigorous branch. May its fruit ripen in the sunshine of favor that sheds lustre on the parent tree. Prof. Wm. H. Thomson, M.D.

Our Sister Departments.—Laboring in a common cause, let us also labor for a closer union. Prof. E. A. Johnson.

Our Sister Alumni Associations.—We rejoice at their continued prosperity, and welcome them through their representatives. Prof. C. R. Agnew, M.D.; Prof. W. T. Lusk, M.D.

Medical Education.—Its object; the accomplished physician, an ornament to society and his profession. Prof. F. D. Weiss.

The Press.—A power mighty for good or ill; may it only be devoted to that which elevates and enlightens. Fred. A. Castle, M.D.

Our Alumni.—R presented as we are in every quarter of the globe, we are honored by the presence of a distinguished brother from the neighboring Dominion. Prof. Samuel Hall.

Our Hospitals and Dispensaries.—For the poor, relief; for the rich, reliance; for all, security. Prof. William A. Hammond, M.D., Class of 1848.

Our Dead.

Woman.—

"For where thou art there is the world itself,
With every several pleasure in the world,
And where thou art not, desolation."

James H. Anderson, M.D., Class of 1860.

Letters were read from Prof. Martin Payne, Parke Godwin, Wm. Canniff, of Canada. John Taylor Johnston, George F. Shradly, and others. The occasion proved one worthy of a place among the pleasant associations of the University.

OUR INFLUENCE WITH THE PUBLIC.—The *Western Lancet*, San Francisco, in commenting upon our recent editorial upon this topic says: "Although our office of Coroner is now filled by a medical gentleman in lieu of an undertaker; that we have a 'Board of Health,' composed of representatives of the profession, instead of these matters being entrusted to laymen; that we have one representative in each branch of our local legislature, and several in the State Legislature, who doubtless will do all in their power to secure proper laws for the moral and sanitary protection of their constituents, and thus contribute their quota to the many reforms necessary; yet, as we have said, there is more to be accomplished, and this can only be done by constant contact with the people; the discussion of subjects with reference to the education of the masses, either from the rostrum of the lecture-room or the daily intercourse of the profession with themselves and with the community in which they may live; the writing of sensible articles for the press, couched in plain yet dignified language, and having the aim in view of benefiting, in some manner, either in health or otherwise, the people to whom it is addressed. We are perfectly aware that these practices are open to abuse, yet what is there that is not liable to abuse? We hold that it is only through these means that the profession of medicine will ever exert that influence over the people that the condition of its votaries entitles it to, and that the people so much need."

We quote the following from the *Chicago Medical Journal*:

THE ABUSE OF MEDICAL CHARITIES.—The New York Medical Record (Sept. 1, 1873) contains an admirable editorial upon "The Abuse of Medical Charities," which concludes with the following: "When a profession can claim to treat gratuitously three hundred thousand paupers annually in New York City, not counting those in hospital, and knows at the same time that one out of every ten of the young medical men in that city can barely earn a living, we think it is about time to look into the matter, to consider whether the occasion is not opportune for proving the force of the proverb, 'Charity begins at

home.' We hope that every reader of the *Journal* will read the entire article and make the application to his own locality, to which it is doubtless quite as appropriate as to that for which it was written. For the little consideration which the medical profession enjoys throughout this country, it is indebted to some of its own members, who, avaricious of practice and notoriety, have sought to acquire them by cheapening their own services, and thus taught society to fix a very low valuation upon that which is eagerly offered without fee or reward.

The world's standard of value is cost; that which costs little is, in the popular estimate, worth as little. At the present time the pay of the average physician is actually lower than that of the average mechanic, relatively very far below; and why? because the public knows it must pay for the services of the mechanic, whereas those of the physician can be obtained for nothing, or, at the most, for a promise to pay, which is never meant to be redeemed, and of which the average physician has not the moral courage to enforce the fulfillment. This cheapening of their profession works a double injury and perpetuates itself; first, by oppressing the young and obscure, whose services are esteemed valueless when the elders hold their own so cheap; and secondly, by thus discouraging the entrance into the profession of those who would maintain its honor and advance its interests. Thus the professional standard is actually approximated to that which it is made to appear, by some pseudo-philanthropists in its ranks. The medical profession appears of late to have abandoned its *esprit de corps*, and its members to have concentrated and individualized their interests; instead of elevating the honor, dignity, and importance of their profession, and therewith their own as of integral parts of it, too many seem to be striving to rise alone in solitary grandeur upon its ruins.

There is one method of elevating the dignity of the profession, and of increasing the value of its services, which is within the reach of every physician; a method entirely within the comprehension of the public, and which it will most thoroughly appreciate, which, if adopted and maintained consistently and persistently, will, in one single year, advance our profession in the public respect to a higher degree than can be accomplished in ten by any other means. The method is this: be strictly conscientious in rendering the best services within your capacity to your patients, and equally conscientious to yourselves in exacting a full equivalent for them, to be paid when the services are rendered; not at the end of the month, quarter, or year, but on the spot. In other words, treat your patient as he treats you. Let us ask no protection for our profession, no privileges, but simply the privilege to protect ourselves.

RANKIN'S ABSTRACT.—We observe the editor of Rankin, while giving notice of the discontinuance of his "Abstract," remarks, there appears to be little need of half-yearly retrospects in that country; but we are enabled to state, by the following extract from a recent communication from Dr. Braithwaite to the American publisher, that his "Retrospect" still continues its original popularity:

"I am glad to say that my work keeps up its popularity in Great Britain, notwithstanding formidable competition. Having been above forty-three years working at bedside practice, it may be that I know what is really wanted, and what is not wanted to be known, and am able to select such matter as is most wanted by busy practitioners; this may be the secret of my success."

Medical Department of Life Insurance.

WHAT EFFECT DOES SYPHILIS HAVE UPON THE DURATION OF LIFE?

By FRED. R. STURGIS, M.D.,

ASSIST. SURG. MANHATTAN EYE AND EAR HOSPITAL, N. Y. CITY.

MR. EDITOR:—Your welcome letter was duly received a short time since, and in it I found enclosed the list of questions you promised me, bearing upon the question, "What influence does syphilis have upon the duration of life as regards insurance?"

The question, sir, is a difficult one to answer, and indeed the reply must in its very nature be approximate, and not absolute, there being so many points upon which no positive reply could be given. Do not, therefore, feel disappointed if, at the outset, I warn you that what I am about to write must be accepted as approaching to, and I trust very closely, the truth, and yet is not the truth itself.

Your first question is, "In the upper and middle classes does syphilis to any extent shorten the 'expectation of life?' in other words, 'Is a man who has had true syphilis as likely to attain the full 'expectation' assigned to him at any given age above twenty-five, as another man of the same age who has not had 'syphilis;' both men, of course, to be in all other respects subject to the same circumstances of life and hygienic influence?"

The mere fact of a man having had acquired syphilis does not of necessity imply that his life is shortened or blighted, and in the upper classes the chances are very largely in favor of his entire recovery from the disease; and by that I mean he will live his life as comfortably and as healthily as his companions who have escaped infection. This applies to the majority of cases; there are, undoubtedly, some whom it would be unwise to accept as risks, but of these I shall speak more fully further on.

Fortunately for the human family, this disease has much abated in severity and virulence since the days of the earlier writers on the subject, since the time of Grünpeck (who was himself a victim), Fracastor, Von Hütten, and others. Then the unlucky wight who contracted syphilis was a pariah and an outcast, shunned by all acquaintance and friends, and doomed to solitude. Were the same course pursued now, dear Doctor, imagine what a howling waste society would become!

The picture drawn for us by these older writers was a truly horrible one, and let us be thankful that we of the present see such but seldom.

Nowadays it is unusual to see the frightful loss of tissue which was not uncommon a century ago, and I think we may safely lay it down as a rule, that the disease seldom goes beyond the earlier stages. In the lower classes, and in those who are neglectful of treatment, or who are subject to some hereditary taint, the disease assumes its worst forms, evincing, as it were, its capacity for mischief.

But even in the lower classes it is surprising to see how seldom syphilis proves fatal. I have compiled the following statistics from the Records of the London Hospitals, and from other sources, and Hospital Records are specially to be preferred, as among the lower classes, who constitute the bulk of patients, the fatality is more likely to be greater than among the upper classes. At St. Thomas's Hospital, in the six years

from 1866 to 1871 inclusive, 130 cases were treated; of these 6 died (a little over 4 per cent.).

At St. Bartholomew's Hospital, in the twelve years from 1860 to 1871 inclusive, 2,292 cases were treated; of these 23 died (a little over 1 per cent.). At the London Hospital, for the three years from 1863 to 1865 inclusive, 209 were treated; of these 7 died (a little over 3 per cent.). At the St. George's Hospital, for the five years from 1866 to 1870 inclusive, 307 cases were treated; of these 5 died (or about $1\frac{1}{2}$ per cent.).

Adding these numbers together, we find the total amount to be cases = 2,938, deaths 41, or nearly $1\frac{1}{2}$ per cent.

I subjoin the statistics in detail. I have used those of the secondary and tertiary forms only, and not the primary or congenital ones, as it would be manifestly improper to do so; the former, because they are not fatal, the latter, because they occur in persons who would not be insured on account of their age.

	Number of cases.	Cured and relieved.	Unrelieved.	Died.	Percentage of deaths to whole No. of cases.	Discharged for other than medical reasons.	Remaining in Hospital.

Total No. of cases..... 2938

" " " deaths..... 41

Percentage of deaths to whole No. of cases..... $1\frac{1}{2}$

I am very sorry that I have so few statistics to present, but would suggest to you, in your capacity as medical adviser to a life insurance company, to find out, if possible, what proportion of deaths among your policy-holders was due to syphilis. In that way only can you arrive at anything settled, as of the hospital cases we do not know how many ultimately died of their disease, nor do I know any way of finding out.

If we turn to the records of mortality in large cities and in different countries, we find that syphilis is not such a fatal disease as compared with typhoid, phthisis, etc. I append for your consideration the mortality figures of New York and Philadelphia for 1871, as

taken from the reports of the State Boards of Health of those cities, and of London, copied from the Registrar-General's Report for the same year:

	Total No. Deaths.	Deaths due to Syphilis.	
New York.....	26,376	142	a little over 5-10 per cent.
Philadelphia.....	16,983	19	1-10 "
London.....	80,434	352	4-10 "

Here are the death records for the United States and England:

	Total Deaths.	From Syphilis.	
U. States, census of 1870.....	492,363	590	a little over 1-10 per cent.
England.....	1871, 514,879	1,742, or	3-10 "

On the causes of death the hospital reports are very vague, but such as they are, I give them you.

Of the six deaths at St. Thomas's Hospital, the cause of only one is given, viz., where the patient, entering in a semi-comatose condition, was found to be suffering from gummata on the internal surface of the left middle lobe and right anterior lobe of cerebrum.

The causes of death among the twenty-three cases at St. Bartholomew are as follows: 1 tuberculosis, apparently independent of syphilis; 9 of exhaustion (2 of these after tracheotomy); 2 of pleurisy and bronchitis, not stated as syphilitic; 1 from peritonitis and exhaustion from anal fistula; and 1 from erysipelas. The causes in the cases of the remaining 9 are not given.

None of the causes of death among the patients of the London are given; and among the St. George's but one, i.e., redema glottidis, from necrosis of the thyroid cartilage and denudation of the perichondrium.

Meagre and unsatisfactory as are the hospital notes with regard to the deaths, one cause strikes us at the first glance as prominent, and that is exhaustion. I pointed out, in a paper contributed to the *American Journal of the Medical Sciences* for July, 1873, how dangerous this form of the disease is, and what bearing it has upon the prognosis. My opinion remains the same as when I first wrote the paragraph, which is as follows:

"One of the most serious, and, fortunately, one of the least common of the results of syphilis, is that known as 'syphilitic cachexia,' where it would seem as though the system, becoming entirely saturated by the poison, had lost all functional and vital power, the patient sinks slowly, inch by inch, in spite of all that can be done, and finally succumbs to some intercurrent disease, the severity of which is entirely disproportionate to the result. As may readily be conceived, the prognosis is very unfavorable."

To revert for a moment to our figures. We find the average percentage to be about 2 per cent., and that, too, in the lower classes, among whom we should expect to find syphilis most fatal. Granting these premises, the probabilities are in favor of the percentage among the rich and well-to-do being much less. One objection may here be urged—and a very pertinent one—that among the better classes every effort would be made to suppress the real cause of death, and that the physician might be unable to assign the proximate or even the remote cause.

But among the lower classes these considerations would be apt to have but little weight, and if among them we find such a small percentage, I think, in the absence of any evidence to the contrary, we may fairly argue the proportion among the upper classes as inconsiderable. Saying it is as much as 1 per cent., would the risk be such a bad one?

Before leaving this subject, my dear Doctor, I may be pardoned if I quote from one who is considered

authority in Germany, and by comparing his statistics see how far they agree with those already compiled:

"The total of syphilitic patients in the various wards of the k. k. allgem. Krankenhaus, in Vienna, for the year 1862, amounted to 1,097; of these 667 were males, 430 females.

"The number of deaths was 8; 6 males, 2 females. Percentage = 7-10 per cent.

"The causes of death were, for the most part, tuberculosis pulmonum, nephritis albuminurica; one woman died from perimetritis septica."

Query 2.—"What are the circumstances (as regards habits, age, occupation, climate, social standing, marriage or celibacy, and physique) which favor or hasten this deteriorating influence of syphilis?"

For convenience' sake I shall divide these various influences into two different groups: 1st, the hygienic; and 2d, the physiological. Among the first would be ranked habits, occupation, climate, social standing, marriage or celibacy; and among the second, physique, age, race, and hereditary tendencies.

To commence with the first group, the first question which challenges our attention is, What part do habits play in this disease?

I must beg you to bear in mind the two groups into which acquired syphilis may be divided, viz.: the benign and the malignant; and this is important, because your opinion will vary according as you have to deal with one or the other. Poverty, misery, insufficient food, and excessive drink, all play their part in intensifying the symptoms of this disease, and transform what might, perhaps, have been a mild attack, into one severe and dangerous. The picture drawn by Zeissl,† as to the effects of dirt, poverty, and defective sanitary measures, is not overdone, and the simple reason why we see so little of it, is because our country is not so thickly populated, in proportion to its size, as is Austria. But here, in New York, those curious in such matters can see some of the effects of these agents by visiting the poor quarters of this city and the dispensaries. Lancereaux (Traité historique et pratique de la Syphilis, 1866), gives a case bearing upon the influence alcohol exercises upon this disease, and its intractableness shall be my excuse for introducing it here.

"A patient who had been under my care for more than a year for a visceral syphilis (of the liver, spleen, and ganglia), finding himself better, and believing himself actually well, thought he might, without danger, abate the severity of the régime which had been prescribed. But an exostosis of the anterior portion of the forehead appeared as the consequence of a somewhat prolonged debauch. Under appropriate remedies this rapidly disappeared. Some while after, the patient, believing himself entirely well, indulged in another debauch, which was followed by a fresh exostosis at the same point."

Occupation has only an indirect bearing upon syphilis, and such trades or business which are in themselves confining or unhealthy, as tailoring, cobbling, and the like, are not the best for syphilitics.

Climate is an important factor in the problem which we are trying to solve, and here is a point where physicians can give advice with better chance of being listened to than where a man's habits are concerned. Extremes of temperature, whether of heat or cold, as well as sudden variations, are bad, and the countries included in what is known as the temperate zone are where syphilis shows its mildest characters.

In summing up the evidence upon this point, Lan-

* Zeissl. Lehrbuch der Syph., etc., 2d ed., vol. ii., p. 83.

† Lehrbuch der Syphilis, etc., 2d ed., vol. ii., p. 14.

cereaux (op. cit.) says: "En résumé, un climat qui varie peu, dont la température est modérée et à peine différente de celle du lieu où la maladie a été contractée est celui qu'à l'exemple de Sydenham on doit rechercher de préférence pour les syphilitiques," and Swediaur in his "Traité des maladies Syphilitiques," t. ii., p. 67, is no less positive when he writes, "La syphilis qui se montre pour la première fois dans un climat quelconque, est très violente dans les effets; mais elle l'est beaucoup plus lorsqu'elle est importée d'un pays chaud dans un climat froid."

Social Standing.—Some of what was said under the head of hygiene will apply here, inasmuch as a good social position preargues more or less comfort and ability to provide for one's health and guard against illness. Bad ventilation, lack of warmth, insufficient or poor food, by acting as so many depressing agents, furnish the disease opportunities for extending its ravages and assuming its worst phases.

Marriage or Celibacy.—Marriage or celibacy, *per se*, influences the course of syphilis only so far as they affect the general health or well-being of the patient, and marriage would perhaps diminish the chances of the later stages supervening by lessening the incentives to debauchery and loss of the general health and strength. But beyond that I think it would have very little influence.

In this connection I would call to your mind Dr. Stark's statistics of the comparative longevity of married and single people, in which the former have decidedly the advantage.

This brings us to the second group, the physiological, under which were included physique, age, race, and hereditary tendencies.

The first, physique, must be dealt with in a general way, for it stands to reason, *cæteris paribus*, that a robust person of strong physique and good constitution will stand a better chance of overcoming the disease than will a weak and sickly one.

The second, age, is perhaps the most important factor in this intricate and difficult problem. As Ricord has pithily put it, "Il ne fait pas bon de prendre la vérole dans la vieillesse," and he might have added, "ni dans la jeunesse." Statistics show that a large percentage of deaths from syphilis occur in those under 5 years of age; but as this does not concern us at the present moment, we may pass it by with this simple notice of it. Most of the authorities of the present day are agreed in the opinion that syphilis, when contracted in advanced life, is more difficult of recovery than when the infection occurs in youth, and a moment's reflection will show how much more likely is a degenerative and exhausting disease to work evil in the aged than in the young and tolerably robust adult.

Race.—There would seem to be good grounds for believing that syphilis is more malignant in some races of people than in others; thus, for example, among the negroes, I have noticed their lesions are more apt to take on the ulcerative forms, and to be less amenable to treatment; and my friend Dr. Charles S. Bull, of St. Louis, in a paper on "Syphilitic Iritis and its Complications," writes thus: "My attention has been called, during the last few months, to the peculiarly unfavorable course which syphilitic iritis seems to run, when it occurs in negroes; and on mentioning the subject to several of my colleagues, I was informed they had observed the same thing." Not only is this the case among the negroes, but among the inhabitants of the islands of the Pacific, and among the Indians of the continents of North and South America. Although, no doubt, partly dependent upon defective hygienic

conditions of life, much of it is, I believe, due to race differences.

(To be continued.)

THE MORTALITY OF PHTHISIS.

SINCE the publication of my report on the causes of 1,000 deaths (MEDICAL RECORD, Jan. 15th, 1874), my attention has been called to the fact that, in comparing the company's mortality from consumption with that which prevails in the country at large from the same disease, no account has been taken of the circumstance that the community of policy-holders differs from the population at large in having among its number no individuals under 18 or 20 years of age, and very few over 65. The comparison we have made, ought, therefore to be modified. From the total number of deaths for 1870, as ascertained by the last census, and from the 1,000 deaths in the company's experience, we should deduct all those which occurred before the 20th or after the 64th year of life. The same should be done in the case of the deaths from consumption. Placing the results together in the form of a table, we have the following:

	Total deaths from all causes, 20 to 65 years.	Deaths from Consumption, 20 to 65 years.	Ratio.
Community at Large.	100,472	24,978	25 per cent.
Company's Experience.	969	263	27 per cent.

In other words, the company's mortality from consumption is but little greater than that which prevails in the community at large.

Bearing in mind the eagerness of phthical persons to insure their lives, and the difficulty of diagnosing the disease in its early stages, especially when the applicant withholds important facts from the examiner's knowledge, I am rather surprised than otherwise that the results are no worse for the company. But I am told by the actuary of the company that a still further deduction—one, however, that is hardly susceptible of being computed in numbers—should be made on account of the withdrawal every year of a large number of healthy lives from the community of the insured, while those who remain comprise among their number an undue proportion of diseased or weak lives. In a community thus peculiarly constituted we should certainly expect a proportionately heavier mortality from consumption and other similar chronic diseases than among the population at large. A. H. B.

THE CHINESE AND THE JAPANESE.*

A COMPARISON OF THEIR PHYSICAL TYPES.

By ED. MADIER DE MONTJAU.

TRANSLATED FROM THE FRENCH BY NORMAND SMITH, M.D., OF NEW YORK.

I SHALL attempt to trace some of the points of resemblance and difference which unite and separate the populations of China and Japan; and, in doing this, my communication will have at least the merit of not

* From the *Revue Scientifique de la France et de l'Étranger*, 10 Jan., 1874.

being borrowed either from the reports of officials, from books or narrations of travellers, or from the conversation of my friends.

I shall limit myself to telling you what I have seen and learned during a long sojourn in the two countries. The majority of travellers are very superficial observers; I desire no other proof of it than those words so often repeated by Europeans, especially as regards the difficulties presented by the administration of criminal justice: "All Chinese are alike, all Japanese are alike." It is very true that among the populations, the color of whose hair is never lighter than dark chestnut, whose complexion never varies except from pale bilious brown to the yellowish or dark bistre of the Caffre or of the mulatto, who almost never have a beard, and whose body is almost always absolutely smooth, among these populations it is true that the individualities will be less striking than among our European populations, where we find the blonde, the brown, the chestnut, and the red. Add to this the fact that both of these populations present in every respect much less striking inequalities than our own as regards form, muscular development, regularity of feet and hands, straightness of the lower extremities, abundance of hair and low grade of type of the skull (*dégénération calvique*). All this is true, particularly when you apply it only to provincial regions. The barefooted and lightly clothed Cooly of Canton is much smaller, more muscular, more swarthy than the peasant of Ning-po or of Sontcheon and of the environs of Shanghai. The latter is generally pale, and when clothed in white or gray, set off by his enormous Tartar boots, looks like a colossus, particularly when dressed in his coarse winter furs. The Japanese of Satsonma and Tosa are nearly black, while at Yedo the men and women are often so white as to efface all recollection of a yellow race. But, taken collectively by provinces, it is true that the men and women in China and Japan are more alike physically than in any one province of Europe, or, more particularly, in any one province of France.

Some of the causes of this are very evident, and they do not appear to me to place our too much boasted European civilization in the most favorable light, neither do they speak altogether well for the Orient or China.

I have reference only to the poorer classes. The various grades of society differ everywhere. In France the higher classes are taller. It is the same in China; and, in that country, while obesity and leanness are rare among the common people, they are frequent, often excessive, among the rich, and particularly in official circles. Obesity may be explained by their way of living, as physical inertia is in honor among the Chinese. Fat people are therefore much respected. In the same way as Caesar was proud of the sobriquet *Felix*, which his soldiers had given him, so the rich Chinese are proud of being fat. "His food agrees with him, he succeeds in everything he undertakes," they say, and all regard him with envy and try to be near him and live under his protection. Leanness is always found among those leading an active life, e.g., the merchants, the shopkeepers, the clerks. Extreme leanness is the lot of the opium-smokers. Hideous leanness is the lot of the beggars, who, although dying of hunger, will sell even their cues in order to obtain the *Indian drug*. These very cues find their way to Europe, where they are used in making chignons.

In Japan obesity or extreme leanness is rarely found. The middle class, less numerous than in China, is much less vigorous than the poor class, but in stature the two classes differ less than in that country.

With regard to the aristocracy, which in Japan is strong and numerous, and in China is composed almost only of office-holders, I will say that in China the aristocracy presents all the popular types, because it is recruited from the *parens* of all classes and all provinces. It presents also a good number of Manchou types, because the Manchous are in favor at court. It must not be forgotten that the famous literary examinations of China are not the only seminary of functionaryism. For example, the viceroy of Canton, one of the best, most judicious, most pacific of men, and most accessible to strangers, is an old Manchou general, and certainly with very little education. There are also mandarins who have become such through the influence of money, with or without examinations.

In Japan the aristocracy is, or rather was, hereditary, with landed estates, and it never contracted those marriages which were formerly called *mésalliances*. We have never seen any type of Japanese aristocracy physically very powerful. Among the monuments of Japanese art we do not find the aristocracy much more beautiful than the rest of Japanese humanity. Only the representations of historical myths make their chiefs herculean demi-gods. Must we believe these popular images of Tatkau-Sama and Co., or admit that the Japanese grandes have degenerated since the Conquest? If we accept the latter view, their condition would be similar to that of the grandes of Spain, who have become the most stunted men of the Iberian peninsula, owing to their system of strict classification of marriages.

I wish particularly to state that the least attentive observer can distinguish in the same provinces races which differ very decidedly from one another. In Konang-toung, for example, the Hakas and the Pountis, both men and women, are very different. The former have more delicate features and more slender forms; they are more laborious, less subtle, more courageous. The inhabitants of Canton are very much feared by the people of the North. The valiant Coolies, who, for eight pisters a month, exposed their lives while placing ladders against the forts of Takou for our soldiers, were from Canton. At Tientsin the porters resemble the Koreans. At Simons-ki also there are many Korean types. At Nagasaki there are many Southonans, and some skins that are very white in spite of a broiling sun and an overheated atmosphere.

I shall finish what I have to say on this point by stating that the yellow races blush accidentally under the influence of emotion, though the contrary has been affirmed. I have myself seen a young and very pretty Chinese girl blush up to the whites of her eyes.

Finally, I will add that in China, to a moderate extent, and particularly in Japan, there are brown complexions so copper-colored as to approach almost to the color of oxide of iron, or of red ochre, and who remind me of the Indians whom I have seen in North America. In China we find, by way of exception, although frequently, heads of such an exaggerated ovoid shape that, were it not for the height of the nose, they would remind us of the Aztecs. In Japan we find the face long or square, the forehead bony, the cheek-bones enormous, the jaws massive, the teeth thick, the skull cubical or ovoid, the forehead flat or convex, but very low, the nose short, broad at the base, but curved; in fact the whole appearance, taken in connection with the complexion, reminds one of the Red-skins. I fear that I shall be accused of scientific boldness, and shall therefore refrain from drawing conclusions. I will simply relate what I have seen. In adding that in the great mass of Red-skins the root

of the nose is scarcely developed, and that although in Japan and China the absence of the prominence of the nose, as far as to the inferior half, is the universal rule, it seemed to me that in Japan this rule is a little less universal in this sense, that we sometimes find a slight prominence of the nose on a level with the iris, especially in individuals of light complexion. This question of the nose appears to me to be one of great importance. I have seen quantities of Chinese of several provinces, also Japanese of almost all regions, except perhaps those of the extreme north, many Malays, a good number of Annamites, and several dozen Koreans, all of whom have scarcely any prominence in the upper half of the nose. The nose of the Malays and Annamites is especially repulsive, as it does not seem to have any bone or cartilage. Whether small or large, more or less flattened, it reminds one of certain kinds of bears and particularly of certain large monkeys; it seems to be composed of skin early wrinkled by age. This nose, more than any other, has a beastly expression. The Koreans generally have the nose proportionately large for their size. Their nose, like their whole body, is more bony than the nose and the body of other yellow races, as far as I have been able to observe them. Among them I have also seen people shaped exactly like Red-skins. Their complexion often borders on a most decided chocolate color. As much as I may fear to be called an heretic, I cannot but insist on the term Red-skins. Red-skins have, like the Chinese and Japanese, well-rounded, almost feminine forms, combined with the greatest athletic development. They have, like the Chinese, the pectoral muscles very little developed; the muscles of the arm less powerful than those of the leg. Their nose, much more bony, more curved than that of a very large majority of the Chinese, differs less from that of many Japanese; the contour is in every respect more ovoid. But one should see the Japanese wrestlers at exercise; they are very numerous, large, fat, generally very well fed; they live a life of indolence and healthful exercise. Look at them quite naked, with their hair fastened up *à la chinoise*, as the ladies say, and tied in the middle of the back part of the head; observe that the skin has often entirely turned to a decided chocolate color, and tell me if they do not remind you forcibly of the Red-skins.

Do not forget that the Red-Skins, the Malays, the Annamites, the Chinese, the Koreans, and the Japanese have the same foot, and that this foot is worthy of attention. The Korean is more bony, the Malay thinner (he is the most debauched, drunken, impudent, wasteful, and quarrelsome, the oftenest sick and the quickest dead); but, among them all, the foot is the same. They make use of it with an astonishing degree of expertness in climbing and seizing, almost as much as do the Indians. But among the latter the foot is longer and narrower, and resembles closely the foot of the ape.

The Sikhs, with a height varying from 1.65 to 2 mètres, have very long and ungraceful feet. This foot of the yellow race is not flat, but low and full. I mean by that that the instep is not very prominent nor bony, and that underneath it does not form the bridge so characteristic of the Spaniards. The ankle is not much above the ground, but the foot is perfectly regular, straight, short, and of good size from before backwards; the ends of the toes almost square, never very callous, even among those who work barefooted, and it is joined to the leg by a very fine articulation. The hand and foot of the yellow race are much smaller than those of the Arabs. I have said nothing of the foot of the Chinese women, made small by mutilation

(and I will treat the subject briefly), because this is the result of custom, and not at all characteristic of the race; only it is not true that this custom is dying out. There is still not one woman in the upper classes whose feet are in a natural condition. The custom varies according to the class and the locality. In the environs of Southeon all rich families cripple their female children in this manner.

At Shanghai, a day's journey from Southeon, this custom is not so general; at Canton still less. In certain country places all the female peasants have undergone this mutilation. It is a fact little known that even adults are often operated upon. At Hongkong I have seen a female servant sixteen years old submit to this torture in order to marry better. At this age, however, they only obtain a misshapen foot.

I have seen women who had been operated upon in infancy, whose feet were scarcely four inches long, walking well without a cane. I have tried to inform myself, and have learned that this detestable operation does not cause near as much mischief as it certainly would in Europe.

The lymphatic constitution of the race helps to remove fever and inflammation.

Nevertheless, I have often seen young girls, six, seven, and eight years of age, carried, being unable to stand, their little legs, banded tightly up to a point above the knee, hanging lifeless.

I am sorry to have to note that at Hongkong the English government closes its eyes to these horrors. It allows a great many others in order to please the Chinese.

To the medical fact just mentioned it may be useful to add others.

Firstly, the fearlessness with which the boldest mutilations are made, and the facility with which they heal in the yellow race, at least among the Chinese; then the different character of the cicatrizations, the action of the weakest medicines, the little havoc which small-pox makes among the natives in the extreme Orient, and its terrible effects among strangers. I shall call your attention, another time, to these facts, in connection with the subject of Chinese medicine.

I have said that among all individuals of the yellow race the pectoral muscles are little developed. I beg you to remember that these muscles pass around, under the arm, upon the back. These muscles sustain the breast of the female, and maintain it in its place. It is the weakness of these muscles, and their small development, which seem to me to explain the admirable roundness of the mammae among all the yellow Oriental women, and its frightful flabbiness as soon as they are old. At these two periods of life, the bosom of the woman of the yellow race is very beautiful and afterwards extremely ugly. The same is true of the women of the Red-skins.

There are certain differences between the Chinese and Japanese women; thus, for instance, the latter have the mamma more developed, often very beautiful, and more permanently so than in the Chinese; the chest, too, is more open and vaulted; the shoulders and neck are stronger and more elegant, the limbs more vigorous, the whole body more plump. The Chinese women, in general, are slender, their shoulders flat and square, the chest sunken.

Perhaps I had better mention several anomalies and some facts in reference to cross-breeding. At Hongkong and at Amoy I have seen two perfect Albinoes: the skin of the whole body, the face included, was of the most characteristic pink. At Shanghai, a jeweller, son of a rich shopkeeper, born long before the arrival of the Europeans in this province, had a long cue of

straight, light-red hair of different shades. His complexion was pale and sallow, his eyes of a dark, reddish green.

Half-breeds are not wanting. It is not necessary to go farther than Hongkong. In that city I remarked four half-breed women, all daughters of native women and Englishmen. All were of a perfect brown color, but with that beautiful light-pale complexion so much admired in Quadroons. One of them had a long, prominent, European nose. The three others were taller than Chinese, stronger, fuller, and really beautiful, though their faces were a little too flat and round. Their eyes were much less drawn at the inner angle. Their hair seemed to be finer, always perfectly straight, but a little less badly distributed than among the pure Chinese women. I shall observe, in passing, that this distribution of the hair is much less defective among the Japanese. The Chinese women in full-dress conceal this defect pretty well with their different national coiffures. Those who desire to please Europeans dress their hair in bands which pass horizontally over the ear. The Japanese never, under any circumstances, change their local fashions; although the Chinese like to get our plain materials, such as stockings, shoes, and ladies' boots, and sometimes jewels. These modifications always begin among the demi-monde, and, strange to say, more so in China than in Japan.

Will the respectable women of the extreme Orient wear the same ornaments as the foolish virgins?

This has happened in other parts of the world. There are also blonde half-breeds. I have seen a boy from twelve to fourteen years of age, finely formed, with light, sandy hair, freckles, clear, rosy complexion, and light-brown eyes; and two lovely little girls, from three to five years of age, with nut-brown hair, blue eyes, white skin, and rosy complexion. It was at Hongkong. Both of these were children of the same Chinese woman, and a well-known Hollander, who did not trouble himself about them, quite contrary to the habit of his countrymen living in Java, who generally do what they can for their unfortunate illegitimate children. I hope that my lady readers will pardon me when I say that I bargained for these two little children for the express purpose of telling them all about them. The *manua* (a *manua* is not a mother, but one who speculates in adopted children) assured me that I could not buy them for a thousand dollars apiece; that she was not rich, but that she preferred to run the chance of their being looked upon as desirable prizes for mandarins of high station; for in this country it is only too true that paternal or maternal authority, even when acquired by adoption or purchase, is unlimited. They sell their little children like lambs or little pigs. On the other hand, I have been assured that the most destitute would not sell their children to Europeans. As to letting them out for all sorts of purposes, that is admitted to be a fact. Moreover, the popular belief is that, among the half-breeds, the males are quietly disposed of by sending them into the interior. This is done, they say, because they are too intelligent, too much inclined towards strangers, though valuable enough to be confiscated, so to speak, to the service of their own country.

At Macao the half-breeds can be counted by thousands. It can be said that the whole town is composed of half-breeds. The Chinese there are more slender than anywhere else. Many are tall, and of a rosy, copper complexion. Many have long and fine features. There is yellow blood in all the European families. These creoles with Portuguese names are almost all well formed, though small, and they often have beautiful features. The women are sometimes very pretty. In

color they are less black, or rather more yellow, or more red than the European Portuguese, but they live in Chinese filth, and nourish themselves about as poorly as the Chinese. At the same time they dress in very elegant style, and are very clean about their persons. Their moral character and the tendencies of their intelligence leave much to be desired. While intelligent and very quick-witted, they are, nevertheless, very ignorant. They are the interpreters of all Southern China, although unable to read the Chinese language, which they affect as much as possible to ignore. Like all the half-breeds, the Portuguese of Macao make fine-looking and good soldiers.

I do not know whether travellers or physicians have ever spoken of the cross between the Europeans and Japanese. Perhaps there is something new to say on this point. I shall be brief. I have seen seven or eight half-breed children in Japan, nearly all of French fathers, and exceedingly beautiful. I happened to be acquainted with these fathers. They were, as regards size, form, and face, above the average, which, among Frenchmen, it may be well to say, is not very high. All these children are remarkable for strength, fullness of features, intelligence, and gentleness. All the mothers, it is true, are pretty Japanese women, and very white. All the children have a rosy complexion, chestnut-colored hair, and black eyes, notwithstanding the fact that the fathers have blue eyes. They also have the characteristic tense condition of the skin at the inner angle of the eye, though only to a slight degree. This tense condition, of which we have already spoken, is more general than the oblique eye, which is found among the Tartars.

Our observations upon the cross-breeding of European races on the one hand, and Chinese and Japanese on the other, will be, for a long time to come, only partial. In fact, for the present time, there is but one kind of union to be considered, whether legitimate or illegitimate, viz., that of European men with women of the yellow race. It is the same in the Philippine islands, at Java, and in India. It will be a long time before white women will have children by men of a race not white, except in very rare instances; whereas European men of to-day do not consider it wrong to procreate with women of any and every color.

Meanwhile it would be well, if possible, to study the relative power of each of the two sexes in cross-breeding. Useful facts on this subject could be collected in Japan only after the lapse of several years, because there are still only a few half-breeds there, and all are children. There are many reasons for hoping that they will occupy themselves more with the education of these poor little bastards in Japan than they do in China; but the chief one is that there are fewer English and Germans in Japan than in China. Let us hope that in a few years we will be able to make some serious observations on half-breeds, not only from a physical point of view, but also with regard to intellectual development and moral tendencies.

Even Macao cannot furnish us complete facts relating to this question, although there, more than in Brazil, Goa, Mozambique, or Senegal, the Portuguese have given proof of a remarkable absence of prejudice in the matter of sexual union. At Macao they are united to Chinese women, to Annamites, Malays, Japanese, and to the half-breed women of all the races. All the half-breeds are allied among themselves, and that, too, since the time of Camoens. But a Portuguese or half-breed woman is scarcely ever united to a man of pure yellow race. Macao can then be only useful to us for the purpose of judging what becomes of the race of half-breeds, and, if we study Macao in this respect,

it will be necessary to take account of the following facts: peopled originally by European bandits of the worst class, living from brigandage and fraud as much as from commerce, rotting for ages in the grossest ignorance and superstition, with a detestable hygiene, Macao was not an atmosphere favorable to the development of a new race.

In the half-breed population of Macao, more than anywhere else, you can convince yourself of the extreme persistence of this, which I consider a special characteristic of the yellow race, viz., the depression of the nose on a level with the iris.

Finally, it seems to me that it is not on the coasts of China, and still less in Japan, that we should expect to find in a pure state the north-west branch of the yellow race. In order to study it, we must go to the south-west portion of the Celestial Empire. The Japanese people seem to me to result from several crossings, which are very curious to analyze. And it would be necessary to go to the northern part of Nippon, at Yesso, and at Saghalien, in order to get a correct idea of this.

If I were to review the striking characteristics common to the whole yellow race, and which make it differ from all other races, I would find two characteristics besides complexion: 1st, The foot, somewhat triangular, the base of the triangle being at the anterior extremity; low, and smaller than all other feet. 2d, The nose flat—or, rather, absent—as far as to its inferior half.

Finally, permit me, in conclusion, to explain myself in a familiar manner. My formula is the result of long experience, and because it is not scientific may not find favor: an individual who can wear bow-glasses easily, does not belong to the pure yellow race.

WHERE LIES THE FAULT?

MR. EDITOR:—I have been much interested in some of the articles in your Life Insurance Department, and particularly those touching the medical examinations, or rather their relation to the physician, the agent, and the company; and a great deal of ink has been shed in fault-finding, in defining the position of the doctor, etc., etc., all summing up with the general statement that matters are very unsatisfactory. I do not propose to analyze the various statements, but beg simply to give a leaf from my own experience, as I have seen nothing from a similar standpoint. I am not a "regular examiner" for any company, but I fill gaps for three companies. That is, in one agency, when the doctor is out of town, I am sent for. In another, the doctor sends for me when a second physician's examination is demanded, as in applications for \$10,000 and over. In another, the agent is my friend, and sends for me when the regular is not to be found. In each of these companies my credentials, with references, are on file at the home offices, and my examinations are received as usual. Under these circumstances I make from one to five examinations per month. From my standpoint, after four years' experience and observation, in addition to careful inquiry made previously, I am satisfied that the fault is in the system and not so much in the men; and, as long as human nature is as it is, what else can we expect? We hear shipowners say to their captains: "No cruelty on my ships." Yet the captain knows that if he does not make a quick trip, he will not be wanted; and so it's "lively there!"

So the company says to its agents: "We want you to be particular as to risks; but don't let any other

company get ahead of you." And the agent says to the doctor: "Be particular; but if he doesn't pass, I'm out just so much." So when it comes down to the doctor, instead of his being the watchful sentinel of the company, he is bound to pass his man if he possibly can, for his friend, the agent, wants his commission; and especially does he try to pass him, if his own fee depends upon it, as in some companies.

Now as to making examinations: how few doctors have enough cases to make them experts! Then, as to the party to be examined, we know that the bulk of men are insured after a process of "boring;" in fact they are talked into it; and for fear "we'll lose him," the doctor is asked to visit the applicant at his place of business, or while he is at his dinner, or even, as in one of my cases, while the man was at work at the anvil.

Then, again, what a difference in examiners! I know of a case of a young man who was nervous over the idea of an examination, and so disturbed was he that the examiner declared he could not pass him, as he had heart-disease. Another examiner saw him, noticed the trouble, engaged him in conversation, calmed his fears, and found him to be a first-class risk.

A case occurred here a short time ago like this: a man wished to insure for \$100,000—in five companies, \$20,000 each. Four doctors called him a first-class risk; two other doctors found hypertrophy and valvular disease of the heart. In view of all the facts, it seems to me that three-quarters of the medical examinations are waste of labor, time, and money, and I am not sure but nine-tenths would be more accurate.

Nor do we have a much better showing, according to Dr. Buck's consumption table, in the cases recommended by gentlemen whose names stand high up in the list of honor and skill.

Now, what is the remedy? I have noticed that long life seems to be natural to some families, and *vice versa*. We often see a comparatively feeble man live, and we cannot see how, to a good old age; and a young man, who never was sick, die suddenly and at an early age, simply because one took care of himself and the other did not. I heard Dr. Winston, of the Mutual Life, New York, say that, after a careful examination of the medical history of that company from its organization, he found that deaths, occurring within the expectant time, bore a proportion to short-lived family history that was remarkable; and that in taking a risk he would give more for a long-lived family history than anything else. Dr. Buck's tables, so far as I can see, point the same way, and it certainly has been my observation through life.

Therefore, as far as I can see now, if I were going to organize a company of my own, I would abolish entirely the medical department, and the sole basis of insurance should be age and family longevity.

The regular rates should be according to age, as per tables of expectancy of life. Then the risks would be divided into classes based on family longevity; the standard to be settled according to the number of generations reviewed and the age of each person. In this way a few or many classes could be made, and a certain percentage above or below the regular rate, according to the class, added or subtracted. This would certainly simplify matters. Of course, there would be minor rules to be made, such as: the applicant at the time to be in good health, that is, his ordinary health, so far as he knows; then the longevity of his ancestry, so far as he knows it, is to determine his place in the first, second, or third class, as the case may be. I am confident that in this way many a young man, whom any doctor would call number one, would

he put down number two or three, while many a man who could not get insured on account of heart disease—though he might carry it twenty or thirty years—would be classified as number two, or even number one, with great advantage to the company. X.

SAN FRANCISCO, Jan. 28th, 1874.

Correspondence.

AN HONEST AGENT NECESSARY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Having been a medical examiner for many life insurance companies for the last twenty-five years, I have very naturally been much interested in the perusal of the various articles written for that department in your valuable journal.

As yet, in my judgment, no suggestion which has been made comes nearer to the desired object than the one in the number for Dec. 15, 1873, to wit: "Secure the best elements of the medical profession." I would not confine these "elements" to those of the profession who may be possessed of the most skill only, but I would require them also to be *honest in every particular*.

The greatest difficulty in many instances lies in the manner of their appointment. The present mode of many companies, I think, falls far short of the true course. For instance, an agent, a stranger in the community, comes in town, and in a short time begins to make inquiries of whomsoever he may meet, like the following: "Who is your best doctor?" "Does he do the most business?" etc. As a matter of course, the person of whom he seeks information invariably recommends the physician whom he employs, be he a homœopathist, Thompsonian, or "root doctor."

Should the agent happen to tilt against two or three individuals who speak favorably of the same medical man, in four out of five such cases said medical gentleman will be appointed regardless of his qualifications.

Another instance: I well remember, a few years ago, an individual in this vicinity who took the agency of one of the best companies in Connecticut. He being a strong believer in the doctrine of *similia similibus curantur*, at once appointed a disciple of that theory. The agent, at the time he caused the appointment to be made, well knew that the *doctor* was not a graduate, had no knowledge of anatomy, and knew no more of auscultation than an old Morgan horse which I had driven for ten years. In fact, he belonged to that number who were called "five-weeks' doctors."

Now, if it is necessary to secure the best "elements of the medical profession" for examiners, it is equally important to secure "the best elements" of laymen to act as agents. When these two objects are attained, I think all will be accomplished that can be. Until the latter course is adopted, an occurrence like the following is quite likely to happen:

An agent goes into new territory to work. He first calls upon *all* the medical men in the vicinity, and seeks to ascertain, so far as is possible, all he can about what might be termed their flexibility of character. Before an appointment is made, he announces that his company does not object to his being present when the examination is made. Should there be no objection to that course raised by the physician, he will then say that he (the agent) "will not ask the medical man to rely solely upon the fee for his ser-

vices, but if business is good he often makes the examiner a nice present when he gets through." Such instances I have known many times in my experience, and, in the case of two agents, far more astounding propositions were made. Another assertion of the writer of the article spoken of is incontrovertibly true, to wit: "We do not believe, however, that a blank can be invented which will throw light upon the question of an examiner's truthfulness and willingness to do his full duty toward the company employing him."

One other thing touching the honesty or carelessness of the agent just occurs to me, and that is the question which occurs in the blank to be filled by the agent, the answers to be made by the applicant. The question is, "Have you ever had any of the following diseases?" Here follow their names. In three instances, during the past season, when making the examinations, I have found a negative answer, when the truth was to the contrary. So far as my experience goes, the application, "filled up," is of but little use to the examiner where he does his duty faithfully.

One or two other points, and I will have done.

In relation to the suggestion of some one of your correspondents, that a "private note" from the medical examiner to the company would be very proper, where the examiner wished to conceal from the applicant (he and the examiner being intimate friends) the real source of his rejection. I think such a course is objectionable, for this reason, that it is upon the principle that if the applicant is rejected it is *always* owing to the medical examiner's refusing to recommend him, whereas his rejection often comes from the home office, even after the country examiner has (and sometimes very properly, to my knowledge) recommended "that a policy be granted." In two instances, in particular, do I remember this to have occurred, and the same company, within twelve months, very justly accepted the same risks, their physical condition being nowise different than when the applications were first made. They are now, and were then (a few years ago), in perfect health. Country medical examiners are not always the ignorant ones in the profession. One word as to the examination of the urine. I think it highly important that the specific gravity should be ascertained in the majority of cases, as well as that the test for albumen should be made.

Please excuse the length of this paper, as I could not well make it shorter, and don't now feel that I have arrived at a satisfactory stopping-place.

D. COLVIN.

CLYDE, WAYNE Co., N. Y., Jan. 25, 1874.

Miscellaneous.

FIVE GENERATIONS, ALL LIVING.—Dr. T. S. Lambert has succeeded in having a photograph taken of a most remarkable group of persons. At one end of the picture is seen an old lady, 94 years of age, seated beside her daughter, who must be nearly 70 years old. The grand-daughter, the great-grand-daughter, and, finally, two great-great-grand-children complete the group. The photograph is unusually sharp in all its details, and the family resemblance is quite striking in the faces of all the female members of the group.

A NEW WORK ON MEDICAL EXAMINATIONS.—Dr. Edward H. Sieveking, Fellow of the Royal College of Physicians, London, has just published a most instructive little book for medical examiners, under the title of "The Medical Adviser in Life Insurance" (J. & A. Churchill, New Burlington Street, London, 1874.)

Original Communications.

PERINEAL LITHOTRIPSY.

By ERNST KRACKOWIZER, M.D.

NEW YORK.

(A paper read before the New York State Medical Society, Feb. 4, 1874.)

WHEN listening to the paper on Perineal Lithotripsy, read by Dr. J. W. S. Gouley before the State Medical Society last year, I resolved to test his method in the first case of vesical stone which I might meet. It differs, and is superior to median lithotomy, so-called, mainly for two reasons: 1st, in that it dilates the wound track, the prostatic portion, and the neck of the bladder, in a more gentle and gradual manner than it is possible to do with the finger; and 2d, in that it renounces beforehand the attempt of extracting a stone beyond the diameter of three-fourths of an inch, considering that the track established by median lithotomy cannot be stretched safely beyond the diameter of one inch without exposing the patient to the immediate and subsequent danger of tearing and contusing the parts which constitute the way for extracting the stone.

I have to report *three cases*, in all of which I had the advice and assistance of Dr. Gouley, and in which I used the instruments kindly loaned by him, adhering strictly to the rules laid down by Dolbeau, with the exception that the incision made in the membranous portion was made by at once plunging the knife boldly down to the groove of the staff, and making the incision larger than Dolbeau does himself.

FIRST CASE.—G. M., 64 years of age, watchmaker, had rational symptoms of stone in the bladder for about eight years. The stone was first detected by Dr. George M. Schweig, of New York, who called me in consultation in April, 1873. The patient was chloroformed, and the bladder extended by an injection of warm water; a lithotrite was introduced, and the stone was grasped several times with a view to make out its size. The largest diameter showed 45 mm.; the smallest, 40 mm., corresponding to very nearly $1\frac{1}{2}$ and $1\frac{1}{8}$ inches. When the stone had been grasped for the last time, the beak of the instrument was turned toward the fundus of the bladder, and, while elevating the handle of the instrument, pushed strongly backward and downward, so that the finger introduced into the rectum could make out the contour of the stone with absolute exactitude. This exploration confirmed what the measuring by the lithotrite had already taught, namely, the presence of an almost round, tolerably smooth stone.

The prostate gland was found moderately enlarged. The detritus adhering to the branches of the lithotrite left no doubt that, at least as far as the surface was concerned, it was a phosphatic calculus. Although the patient was well nourished, and although the local functional disturbance was not of an excessive kind, yet he was feeble, and looked pale; so that it was thought advisable to subject him to a tonic regimen for a couple of weeks before the operation should be made. The operation occurred May 20th, 1873. After dilating the track in the manner described by Dr. Gouley in his paper, the stone was reduced to fragments, partly by Dolbeau's and partly by Gouley's lithoclasts, and these fragments and the debris extracted. To do this it was necessary to introduce the instruments very often. The hemorrhage was insignificant. The fragments and debris weighed 1,324 grs. For an hour or two after the operation the patient felt chilly. Ten grains of quinine were administered

at once, and a suppository of opium was given. With this exception and a few five-grain doses of quinia no medication was used. There was hardly any febrile movement, the pulse never exceeding 100°, nor the temperature more than 99° and a fraction. The patient had control over the sphincter of the bladder during the first twenty-four hours after the operation, although the nismus occurred very frequently. These intervals between micturitions became longer and longer, until at the end of five days he could hold the urine from four to five hours. Already the next day after the operation, part of the urine passed through the meatus, and from the fifth day by far the largest part of it was discharged through the natural channel, only a few drops oozing through the wound during the act of passing water.

On the 11th day after the operation the patient was permitted to rise and move around the room. The 14th day after the operation I found the old man sitting at his work-bench. There was only some superficial suppuration at the wound, and ten days later it was completely closed. Dr. Schweig, who was most assiduous in carrying on the after-treatment, and who took very full memoranda of the case, injected the bladder June 6th,—seventeen days after the operation, and sounded it. Not a trace of debris could be detected with the sound, nor did any come away while the patient voided the bladder from the injected water. The sexual power, which had been quite dormant during his sufferings, returned after a few months, and in every other respect the health of Mr. M. has been excellent to this very day.

SECOND CASE.—A rachitic boy, A. P., three years of age, had wetted his bed during sleep as long as he had lived. Had suffered from acute rheumatism not quite one year ago, which left him with insufficiency of the mitral valve. Rational symptoms of stone in the bladder developed soon after, but were judged to be merely an aggravation of the enuresis, which in turn was supposed by one physician to be caused by a too narrow prepuce. So he incised it, without affording any relief. Dr. L. Conrad saw the child, and on examination with the sound detected a stone in the bladder. He invited me to see the child, and by repeating the examination I corroborated his diagnosis. An examination per rectum revealed the size of the stone, in all diameters, to be about three-fourths of an inch. June 3, 1873, Dolbeau's operation was performed. The dilatation was made with Dolbeau's dilator, very slowly and cautiously, but finally the instrument was expanded to its full limit. Gouley's forceps for fragmentation of stone was used, by which the stone was broken up in several small fragments and a powder, which, partly with this forceps, and partly with a slender stone forceps, were removed. Bleeding very little. The stone was a phosphatic one, its weight being about two drachms. There was no reaction. In fact, the child had, since several months, not had so much uninterrupted sleep as the night following the operation. The passage of the urine through the whole length of the urethra did not occur before the fourth day after the operation, and it was fully two weeks before the whole urine came through the natural channel. At what time precisely after the operation the child gained control over the sphincter of the bladder, I did not succeed in making out; partly through inattention of the parents, partly because the habit of wetting himself complicated the case. When I last heard of the child—about three months ago—it was free from all urinary trouble, but the enuresis persisted as much as ever.

Some time ago Dr. Gouley informed me that he

thought the mode of dilating the track for the extraction of vesical stone could be improved; that for Dolbeau's dilator a better instrument could be substituted; that he was experimenting to perfect such a substitute. I show it here. It consists of a gum-elastic catheter, around which, at some distance from its vesical as well as other extremity, a loose india-rubber bag is fixed, which can be filled with water through a small feeding tube attached to its lower end. I promised that I would try it on the first case of vesical calculus that came under my care.

Soon after, my attention was called to Dr. W. Molesworth's so-called climax dilator, which, without doubt, is superior to Gouley's instrument, because the former's tubes, requisite to dilate the track in perineal lithotripsy, can be very easily introduced by the guidance of the staff in the bladder; whereas in Gouley's, the collapsed bag, forming, as it were, two lateral wings, which cannot be easily managed, obstructs the progress of the instrument in the track. Besides, the walls of the bag are too delicate, and even if expanded by injected water, would hardly have force enough to overcome the resistance of the prostate and the sphincter vesicæ, which would rather constrict the dilator, giving it an hour-glass shape.

On the contrary, in Molesworth's dilator the walls of the india-rubber tube are made very strong, and it requires considerable force to overcome its resistance, and to fill it by degrees. The powerful condition of its walls is best seen by opening the stopcock after the distention has been completed, the water being thrown back with considerable force. A case for trying the improved modification soon occurred.

THIRD CASE.—P. W., some forty years of age, was laboring from chronic enteritis and colliquative diarrhœa for seven or eight years. He entered the German Hospital in the city of New York during the summer of 1873 in a state of extreme exhaustion, having hardly any command of his stools, so that he had to pass sometimes many hours on the bed-pan, he not knowing when a passage was coming from him, or, if knowing, not being able to leave the bed to check its running from him. By careful nursing and treatment he improved by degrees so much that he could sit up again, and his appetite returned somewhat. The number of his stools was reduced to four or five in twenty-four hours, and they gained somewhat in consistence, although never assuming a solid condition. About October, 1873, he complained of a more frequent desire to pass urine; that the act was painful; and that the urinary tenesmus continued some time afterward. These troubles increasing, the house-physician explored his bladder with the sound, and detected the presence of a stone. The patient was immediately transferred to the surgical room, in which I happened to be on duty. After a few days' rest I repeated the examination, and found the house-physician's diagnosis correct. The diameter of the stone, as measured with the lithotrite, was 45 mm., about 1½ inches. On touching it per rectum in the manner described in the first case, it was found that the stone was quite round, all its diameters being equal. The next few days of rest were devoted to a careful and repeated examination of the urine. Besides some mucus, it contained albumen; and in each specimen, looked at through the microscope, a large number of fibrinous casts were seen, showing that not merely the excretory portion, out even the secretory portion of the urinary organs was gravely diseased.

January 13th, 1874, I proceeded to subject this most unpromising case to the operation of perineal lithotripsy. Patient was etherized, and after the opening

of the membranous portion of the urethra an attempt was made to introduce Gouley's dilator. I substituted Molesworth's, taking tube No. 2, which allows an expansion of one inch diameter. It was withdrawn while still dilated to its full extent, and it was beautiful to see, as it emerged by degrees from the perineal wound, how inconsiderably wider the parts liberated from its constriction bulged out than the one still retained. The finger could at once be introduced through the track into the bladder. Some little delay occurred in getting hold of the stone, but after it once was grasped it broke up with the greatest ease in a few small fragments and a large amount of dust, all of which were removed by repeated introductions of a slender, common stone-forceps. The stone was a uric calculus, and weighed nearly half an ounce. There was hardly any bleeding. My fear that in an individual so utterly broken down by chronic diarrhœa, with kidneys so much disorganized, the reaction might usher in a suppression of urinary secretion and uræmia, was happily not realized. On the contrary, he bore the operation uncommonly well. The same evening, after the operation, he was conscious that he had some control over his bladder, although he was obliged to expel small quantities of urine every half hour. The next day these intervals lengthened. On the third day a few drops of urine appeared in the meatus, and forty-two hours after the operation he could hold his water for five hours. On this plane he remained for several days, but then his diarrhœa returned with the old force again, and the liquid stools pass from him many times involuntarily. He is therefore many times not able to say whether the urine too passes involuntarily with the stools or not. With all that, the wound has a good aspect, and two days before I came away it looked as if the diarrhœa had been brought again somewhat under control, and he was again able to hold the urine for an hour or so at his will. There is some prospect then that the wound may close, and the urine be discharged through its natural channel, although sooner or later he must succumb to the trouble from which he has suffered for years.*

A NEW METHOD FOR THE TRANSFUSION OF BLOOD.

By JOSEPH W. HOWE, M.D.,

VISITING SURGEON TO CHARITY HOSPITAL, N. Y.

The operation for transfusion has varied but little during the past five hundred years. It was brought fully into public notice during the latter part of the fifteenth century, by the physician of Pope Innocent VIII., who sacrificed three young boys in performing the operation on his master. The transfusion was made with instruments resembling those employed at the present day. Since that period Silarius, Wren, Denys, Riva, Manfred, Playfair, Solon, Jacobi, and many others have operated in much the same manner with varying success.

The ordinary method of operating may be briefly stated thus:—A healthy adult having been selected, and his arm bandaged above the elbow, an incision is made in the median cephalic vein, and from four to six ounces of blood abstracted. This is received into

* The patient died from exhaustion, February 12, 1874 (eight days after the reading of this paper). The post-mortem showed the wound of the operation healed with the exception of a track, passing from the membranous portion of the urethra to the surface of the perineum, admitting a common probe.

a warm bowl prepared for the purpose. The fibrin is then separated from the blood by stirring it briskly or "whipping" it with a glass rod. A vein is opened in the patient's arm, and a canula introduced which is retained by means of a ligature. The transfusion syringe is filled with the defibrinated blood, and its contents injected through the canula into the vein.

Many varieties of syringes or aspirators have been used for transfusion, but the essential parts of the process remain unchanged, and are still open to grave objections.

1st. The blood is exposed for a length of time to atmospheric influences, and therefore liable to receive deleterious ingredients. This is especially liable to occur when the operation is made in the wards of a hospital.

2d. In the process of "defibrination" a quantity of red globules must necessarily be entangled in the meshes of the fibrin, and removed with it. And as the nutritive and stimulating properties of the blood depend mainly on the presence of these globules, a diminution in their amount is followed by a corresponding deterioration.

3d. In cases where the hemorrhage has been great, and the stimulus of healthy blood needed at once, the time spent in defibrinating may render the transfusion a failure.

4th. The wounds in the veins being comparatively large, there is more or less danger of phlebitis or thrombosis.

For some time past I have been experimenting with Dieulafoy's aspirator; and by means of appropriate needles, tubes, and stopcocks, have succeeded in simplifying the method of transfusion, and obviating the objections previously enumerated.

The hollow needles best suited for the purpose are three inches in length, with a diameter of $2\frac{1}{2}$ millimetres. The open space at the end is a quarter of an inch in length; and the point is curved forwards so that on inserting it into the vein its point will not catch in the opposite wall of the vessel. The tubes may be made of rubber or gum, and are five inches in length. The canal of the tube is one-half the size of the ordinary tubing belonging to the aspirator. The stopcock of the aspirator is regulated by the addition of a pivot on the inside, so that the surgeon can ascertain positively when the communication between the aspirator and tube is open or shut. The size of the needles is also required. The aspirator, with the transfusion needles, canulas, and tubing, were manufactured for me by Mr. W. F. Ford, of Caswell, Hazard & Co., and are admirably adapted for the purpose.

When ready for use, the aspirator is placed in a basin of warm water and allowed to remain there from the beginning to the termination of the operation.

A healthy adult with good-sized veins is to be selected, and a broad roller bandage tied around the arm above the elbow, care being taken not to make the bandage so tight as to prevent the circulation through the arteries. The forearm is then partially flexed, and the hand made to grasp tightly a round piece of wood or other hard substance. By this forcible contraction of the muscles the blood is driven into the superficial veins, and the bandage prevented from pressing on the brachial artery. When the vessels are distended the needle is inserted obliquely from above downwards into the median basilic vein. The operator grasps the rubber tube between the thumb and forefinger, turns the stopcock of the aspirator, and allows the blood to rush on and fill up the cylinder. By compressing the tube occasionally the blood will not be drawn out of the vein more quickly than it enters.

In the mean time, a vein in the patient's arm should be exposed. An assistant grasps the arm above the elbow, and presses on the basilic and cephalic veins. These vessels are thus made sufficiently prominent to guide the operator in his incision. An incision is next made through the integument and fascia, an inch above the elbow-joint, and on the inner side of the cephalic vein. The distended vessel will then bulge into the opening. The air is expelled from the tube on the opposite side of the aspirator, by forcing a little blood through it, or by sucking out the air and afterwards compressing the tube between the thumb and forefinger so as to prevent its re-entrance. The needle is then inserted into the vein and the healthy blood thrown from the aspirator into the circulation of the exsanguinated patient.

When the vein is empty, or so small as to prevent the introduction of the needle, a canula may be employed. To do this the vein must be isolated for about an inch, and two ligatures passed around it. The ends of the lower ligature are crossed over the vein, brought down below the arm, and tied. This will prevent bleeding when the vein is opened. The wall of the vein is next pinched up with a forceps, and an opening made through it with sharp scissors. The canula is inserted, the upper ligature tied over it to keep it in place, and the blood injected as before.

Two weeks since I operated by this method on a patient in Charity Hospital, who had lost large quantities of blood from epistaxis. The history of the case as taken by Dr. M'Bride, house-surgeon, is as follows:—

Mary Gibson, age 40; occupation, housekeeper; was admitted to Charity Hospital on Dec. 29, 1873. She gives no history of hereditary disease. Six years ago a tumor was taken from her uterus, in Bellevue. Menses ceased in June, 1873. In October last had severe epistaxis for the first time, and lost (she thinks) about two pints of blood. One month from that date she lost a similar amount. Did not bleed again until the day before her admission, when she had another severe attack. On admission the bleeding had ceased, but she was extremely pallid and feeble. The next day the hemorrhage came on profusely, but was controlled by the persulphate of iron. In three days it returned again, and was checked in the same way. On Jan. 6th, she lost a large quantity of blood during the night, and the posterior and anterior nares were plugged to stop the flow.

I saw the woman on Jan. 7th. She was extremely prostrated, nervous, and incoherent. Her pulse was very weak, rapid, and irregular, and at times almost imperceptible. The skin was cold and perspiring, pupils widely dilated, and voice husky. I proceeded at once to perform transfusion, assisted by Drs. John H. Ripley and Leroy M. Yale, visiting surgeons to the hospital. I abstracted, by means of the aspirator, four ounces of blood from the median basilic vein of a healthy man. Two days before, I had taken eight ounces from the same individual. I made the second opening in the vein a quarter of an inch below the first. The latter had healed a few hours after the operation, and at the second transfusion was scarcely perceptible.

The blood thus obtained was injected into the cephalic vein of the patient. In a few moments she expressed herself as feeling better. There was an immediate and marked improvement in the volume and force of the pulse. This was so perceptible as to be noticed by all present, and prevented me from transferring any more blood. She was then ordered thirty drops of tinct. opii, and a tablespoonful of whiskey. The next morning I found her pulse still improving,

and her general condition excellent. She spoke in a clear voice, and stated that she could think clearly, and remember all her sickness, which she could not do before the operation.

The hemorrhage has not since recurred, and the patient has regained her strength.

I will not undertake to say that this woman would have died if the transfusion had not been made. There is, however, no doubt that the addition of four ounces of blood to her depleted system gave her the stimulus needed, produced an almost instantaneous change for the better in her general condition, and hastened her recovery.

The advantages of the operation I have described may be summed up in a few words:

1st. It takes less time than any other.

2d. The blood is transferred without exposing it to the air.

3d. The nutritive elements of the blood are not diminished.

4th. As the fluid is drawn into a vacuum, there is no danger of coagula forming. (I have allowed blood to remain in a cold aspirator twenty minutes, and at the end of that time found it perfectly liquid.)

5th. The opening in the vein being a simple needle-puncture, there is less danger of phlebitis or thrombosis.

Like all other operations of this character, care and delicate manipulation are required.

The needles and tubes through which the blood is carried to the aspirator must be of the size I have described. On the opposite side, the tube of exit and canula should be larger. The bandage should be allowed to remain on the arm from three to five minutes before the vein is opened, in order to insure complete distention of the superficial vessels. The needle may be inserted into the vein about an inch.

If the vein is small, or the circulation sluggish, compression of the tube by the fingers of the operator will diminish the amount of blood coming from the vein, so that it will not collapse. In all cases it may be well to observe this precaution.

When the proper transfusion needles or tubes are not at hand, the old operation may be performed, and the aspirator employed instead of the ordinary transfusion syringe.

NEW YORK, Jan. 24.

CENTRAL GALVANIZATION COMPARED WITH OTHER METHODS OF USING ELECTRICITY.

By GEORGE M. BEARD, M.D.,
NEW YORK.

I HAVE applied the term *central galvanization* to a distinct method of using the galvanic current in medicine. In this method one pole (usually the negative) is placed at the epigastrium, while the other is passed over the forehead and top of the head, by the inner borders of the sterno-cleido-mastoid muscles, from the mastoid fossa to the sternum, at the nape of the neck, and down the entire length of the spine.*

The object in this method is to bring the whole central nervous system—the brain, sympathetic, and spinal cord—as well as the pneumogastric nerve, under the influence of the current.

The method of central galvanization is based on

these two assumptions, both of which seem to me justifiable.

1. That in a very large number of diseases, and especially of the so-called functional diseases, the pathology is not exclusively confined to any region of the brain or sympathetic, or spinal cord, but the whole central nervous system is invaded by a condition of exhaustion and irritability. I believe this to be true not only of hysteria, chorea, and of many affections allied to them, but of certain states of neuralgia, and a number of diseases of the skin. It is possible, furthermore, that some diseases that are not now regarded as in any respect of a nervous character may in the future be shown to depend so closely on the nervous system that they can be most successfully treated, not through their varying and local manifestations, but through the brain, spinal cord, and sympathetic. That certain diseases, not primarily nervous, do so affect the nervous system that they need to be treated, in part at least, by remedies that act on the nerves, will be conceded, I suppose, without question.

2. That the nutrition of the central nervous system will be improved by passing through it a mild galvanic current.

That in the great majority of cases of so-called functional nervous disease, and in many of the cases of special structural lesions, nerve-tonics are indicated, will be questioned by no one. It is also coming to be pretty generally admitted that electricity is something more than a stimulant—that it is a *tonic* with a powerful *sedative* influence. Still further, it is admitted that the sedative and tonic effects of electricity can be obtained by passing the current, with little or no interruption, through any part, the nutrition of which needs to be improved.*

The positive pole (anode) is applied over the head, neck, and spine, because it is less irritating than the negative, and tends to diminish irritability. The majority of the cases for which central galvanization is used are in a condition of abnormal irritability, and need the calming effects of analectrotonos rather than the irritating effects of catalectrotonos. To this rule there are individual exceptions: there are cases that appear to be benefited more by the negative than the positive pole.

The negative pole (cathode) is placed at the epigastrium, because the epigastrium is a good, indifferent point, that will bear well the irritating effect of catalectrotonos. In order to avoid over-irritating the stomach and the pneumogastric nerve, it is well, in very sensitive patients, and when long applications are used, to change the position of the negative electrode by moving it up and down between the sternum and abdomen.

The positive and negative modifications that take place at the breaking of the galvanic current, in the region of the anode and the cathode, probably complicate somewhat the effects of treatment—are, indeed, factors of some importance in producing the effects, and not unlikely explain, in part, the disagreeable results that come from too frequently interrupting the current when treating nerve-centres.

I claim for central galvanization a distinct and separate position among the different methods of using electricity in medicine. The application of the galvanic current to the head, the neck, and the spine, which have been variously used by electro-therapeutists since the time of Remak, are simply forms of local-

* This method was first described by me in THE MEDICAL RECORD, December 15, 1871, and subsequently more in detail in the New York Medical Journal, October, 1872.

* For demonstrations of the effects of the faradic current on nutrition, see account of my experiments on a litter of puppies, recorded in my pamphlet on "Certain Queries in Electro-physiology and Electro-therapeutics," reprinted from Psychological Journal.

ized electrization, since the object aimed at in all of them is to localize the current, so far as possible, in the brain, or some portion of it, in the cervical ganglia of the sympathetic, or in the spinal cord. Then, again, in all these forms of localized galvanization of the nerve-centres, the poles are placed near each other over the part to be affected, and the peculiar action of both poles is felt, so far as is possible by external application, in the organ that is treated.

In galvanizing the head, for example, the poles are applied behind the ears, or in front of them, or one is placed on the forehead, and the other on the occiput or at the nape of the neck. In galvanizing the cervical ganglia of the sympathetic, one pole is placed on the auriculo-maxillary fossa, or along the inner border of the *sterno-cleido-mastoid* muscle, while the other is applied at the back of the neck. In galvanizing the spine, one pole is placed at the upper or lower part, while the other is passed up and down the entire length, or kept in one place, or both may be moved up and down the entire length, or confined to any portion as is desired.

But in central galvanization the electrodes are so placed that the whole central nervous system is brought under the influence of the positive pole of the galvanic current at one sitting, and without any important change of position of the negative pole. Besides, the central nervous system, the pneumogastric, and the stomach itself are also affected; in a word, the great centres of life, of health, and of disease.

Comparing central galvanization with general faradization, we find most important differences. In the one, only the galvanic; in the other, only the faradic current is used.

In general faradization the application is made not only over the central nervous system, but over the entire trunk, and especial attention is given to the muscles of the abdomen and extremities. In central galvanization the chief aim is to affect the central nervous system; in general faradization the chief aim is to affect the muscular system, although the nervous system, central and peripheral, is affected both directly and reflexly.

Comparing central galvanization with other methods of using electricity, by the effects, we find differences of a most marked and interesting character exist. The ordinary methods of galvanizing the cervical sympathetic, the brain, or the spine, do not, either singly or in combination, produce the powerful tonic results that are frequently obtained by central galvanization. Sedative and tonic effects are unquestionably produced by these local methods, but they are frequently inferior in quality and degree to those derived from central galvanization when properly administered. This conclusion is derived from actual trial and observation of cases. Neither the temporary nor the permanent effects of localized galvanization of the brain, of the cervical sympathetic and pneumogastric, or of the spine, are as satisfactory in many cases, even when they are successively used at the same sitting and with the same time and strength of current, as central galvanization.

Still further, experience teaches that the method of central galvanization, in its completeness, is more serviceable than partial or incomplete applications of it. Placing the negative pole on the epigastrium, and the other on the spine, will not accomplish the full effects of central galvanization, although, so far as it goes, it is a good method and produces sedative and tonic effects. To confine the attention to the head and neck alone, also, is not sufficient.

Comparing the effects of central galvanization with

those of general faradization, I find that both are powerful tonics, and are adapted for conditions of debility, by whatever names they may be known. For some cases, and particularly for cases associated with great muscular debility, general faradization is more effective than central galvanization. On the other hand, in cases where simply exhaustion of the nerve-centres is the leading condition—as hysteria, chorea, and so forth—central galvanization is oftentimes far superior to general faradization.

Some of the best results that I have yet seen have been secured by combining or by alternating the two methods.

Sometimes, after general faradization has done all that it is capable of, central galvanization, rightly used, helps to lift the patient still higher. In cases where I am not experimenting, and seek only the best good of the patient in the shortest time possible, I use in succession, or alternation, and with changes and modifications, all the principal methods—local galvanization of the brain, of the cervical sympathetic, and spine, general faradization and central galvanization.

This course is found to be oftentimes justified by the results.

The improvement is more positive and more permanent than when a single method is used exclusively.

Some cases I treat one week by general faradization, the next week by central galvanization; sometimes I alternate the methods from day to day.

There are, however, cases not a few, where all forms of faradization, and where the local galvanization and the nerve-centres irritate rather than benefit, but in which, under the method of central galvanization, there is sure and constant improvement. I have demonstrated this not only in hysteria and hysterical diseases, but in some forms of eczema and prurigo.*

Dr. Althaus, of London, in the third edition of his most excellent work on Medical Electricity, after describing this method of mine in detail, remarks that he had never carried out the method in its entirety, but that he had used, experimentally, applications to the head and neck with the anode, and to the epigastrium with the cathode. He states that unpleasant results have followed these experiments, that disagreeable cerebral symptoms were produced by it during the application, and which sometimes continued for twenty-four hours or more afterwards.

"The patients had a general sensation of *malaise* and nervousness, headache, and a feeling of giddiness and confusion."

Dr. Althaus further states that he has used the "application of the anode to the cervical and lumbar spine, and of the cathode to the pit of the stomach with advantage."

Nothing is easier than to produce these unpleasant results in susceptible patients by any method of galvanizing the brain and neck, provided strong currents are used, or interruptions are allowed, or the applications are prolonged. The same effects may follow general faradization and galvanization.

In beginning to treat a patient by central galvanization, we should use very mild, scarcely perceptible currents, particularly around the head and neck, and even on the cervical spine, and great pains should be taken to avoid breaking the current, and the application should be of only a few moments' duration. Taking these precautions has now become with me a mere matter of routine, and I am every day accustomed to treat the most sensitive and delicate patients—cases of hysteria, nervous exhaustion, hypochon-

* See MEDICAL RECORD of Dec. 15, 1873.

driasis, and allied affections—cases which are sufficiently familiar to all American physicians, and with sedative and tonic effects that are not obtainable by other methods.

Whenever any of the disagreeable effects spoken of by Dr. Althaus occur, I always give the patient a longer interval, and moderate the applications until only good, unmixed with evil effects appear.

The American constitution is more susceptible to electricity than the English or the German, and if our nervously exhausted, hysterical women can bear and be profited by central galvanization, surely the women of England and Germany might be treated by the same method, even when used with less caution.

I have frequently treated by this method delicate women who are too feeble to walk or stand, or even to sit up, and who, therefore, must be treated in bed, and even in such cases, the disagreeable effects only occur now and then, and no oftener than they occur when other methods of electrization are employed in the same kind of cases; indeed, not so frequently as they follow general faradization or local galvanization of the brain.

I have room to give but one illustrative case. This case, however, is typical of a class of symptoms that, in women especially, are frequently very distressing, and very rebellious not only against ordinary medication, but also against faradization, general or local.

Hysteria of one year's standing in a married lady, following parturition; strange and indefinite sensations in the legs; tickling, crawling, pricking, waving, beating, pounding, heaving, rolling sensations over head and body; imaginary swelling of the body; fits of weeping and great despondency. Rapid and decided improvement under central galvanization with strong currents, after failure of general faradization. Cod-liver oil emulsion and counter-irritation used at the same time.

Mrs. B., a married lady with two children, was referred to me November 5, 1872.

The patient, though a lady of unusual intelligence and great strength of will, had for nearly a year been a victim to many of the worst symptoms of hysteria. The symptoms appeared ten days after the birth of her second child; up to that time her health had been almost perfect. She came from a family in whom there was some tendency to consumption, and she had lost two sisters by that disease. A short time before the birth of her second child, she had fallen down stairs and had struck on the back of her head. The query arose, whether that might not have had something to do with her disease. The symptoms came on in the night, and quite suddenly. She became excessively nervous, almost wild, and the physician was sent for and succeeded in calming her; then followed a long catalogue of woes. On the top of the head was a constant sensation of shaking or agitation, or thrilling, as she described it, and heaving, rolling, beating, waving, pounding sensations were felt in the head and over the body. There had been many attacks of weeping; at all times, though naturally hopeful, she was cast down, and imagined she did not love as she should one of her children. The general nutrition, as usual in such cases, was well maintained.

The patient had tried, with great thoroughness, general faradization but without substantial service.

I used on her mainly *central galvanization*, combined with the use of cod-liver oil emulsion, and mild counter-irritation over the tender vertebrae.

The patient, with all her nervousness, bore the *galvanic current in enormous doses*; it seemed to be im-

possible to injure her by over-electrization. I soon found that the stronger the currents, and the longer the applications, the greater the benefit. Even through the brain strong currents, now and then interrupted, did no harm. She soon began to improve, and continued to improve not only during the three months of treatment, but subsequently, and there was in this improvement a considerable degree of permanency.

In the above case there were facts of great interest. First, the extraordinary tolerance in a highly nervous patient of the galvanic current; and secondly, the supreme advantage of central galvanization over general faradization in severe functional diseases of the central nervous system.

A condition where the superiority of central galvanization seems most apparent, is that which so often accompanies the "change of life." Many of the symptoms of this familiar nervous state are similar to those recorded in the case above detailed. Such cases I have continually under treatment, but to record them would make this article longer than I had intended. In all, or nearly all of these cases, I use central galvanization in preference to other methods.

THE TUNING-FORK

AS A MEANS FOR

DIAGNOSING PERFORATION OF THE MEMBRANA TYMPANI.

By THOS. F. RUMBOLD, M.D.,

ST. LOUIS, MO.

DURING the month of April, 1869, I suffered rupture of the tympanic membrane by a severe explosion that occurred in making oxygen gas with the sulphuret of antimony, instead of peroxide of manganese, by mistake.

By this accident I became acquainted with a phenomenon which is of great value in diagnosing rupture or perforation of the membrana tympani.

In the examination of aural affections,—explaining how I wished patients to observe the well-known variations of sound of the tuning-fork, I had often applied this routine to myself. After recovery, except laceration of the membrane, and in making repetition of this application to myself, I was greatly surprised that by *closure of the auditory meatus* by pressure on the tragus, I could not detect the variation that I had frequently heard previous to the injury.

Very naturally, on the same day I tried this method of examination on two patients then under treatment, and both of whom I knew by ocular inspection to have perforation of the drum-head, and found the same result. I then in like manner examined every other patient, and in *no instance* found that in the ear having a perforated membrane, did the sound of the tuning-fork increase by closure of the auditory meatus.

With each of eight membrana tympani that were operated upon for the insertion of the "Politzer eyelet" to increase the hearing, the sound of the fork was increased by stoppage of the auditory canal previous to the perforation, *but not after it*. In six of these cases, after they were closed by granulation, I found that pressure on the tragus again caused increase of sound of the tuning-fork. With each of three membrana tympani having traumatic opening, closure of the meatus did not increase the sound of the tuning-fork; but after the perforation had healed, sound was increased by this procedure.

In conclusion, I would add, should the Eustachian tube in any case of perforated membrana tympani be impermeable, this will be the only certain means of detecting this condition, especially if the opening be small and hidden.

Progress of Medical Science.

A NEW SOLVENT FOR PHOSPHORUS.—Many attempts have recently been made to obtain a tolerably stable and agreeable preparation for the administration of phosphorus in pills. Mr. Gerrard, of University College Hospital, by using resin as a solvent, has greatly simplified the administration of phosphorus as a drug. Its preparation is as follows: Take a strong, wide-mouthed, well-stoppered bottle and weigh it; then melt a quantity of ordinary resin sufficient to fill the bottle; let the bottle be warmed; then pour in the resin to nearly but not quite fill the bottle, and reweigh, and for every ninety-six parts of resin take four of phosphorus. Now observe that the resin is in a fluid state; if so, add the phosphorus and fix the stopper tightly. Place in a sand-bath previously warmed, and apply heat to 200° centigr., or 392° Fahr. Digest at this temperature and shake frequently until the phosphorus is dissolved.

The further details of the manipulation are given by the *Pharmaceutical Journal* of Dec. 6th, viz.: Take of the phosphorated resin (4 per cent.), twenty-five grains; powdered white sugar, seventy-five grains; tincture of tolu, a sufficient quantity. Pulverize the resin, mix with the sugar, and form into a paste with tincture of tolu—eight to ten drops are sufficient—then divide into twenty pills; each pill will contain one-twentieth of a grain.—*The Lancet*, Feb. 14.

THE DELIRIUM OF INANITION.—The nature of the delirium of inanition was recently discussed incidentally by Sir William Gull at the Clinical Society. Dr. Haust describes (*Le Progrès Médical*, Jan. 3d) the symptoms observed in three cases who practically died from this cause, being the victims of cancer of the stomach. The first, a man aged fifty-five, took only a few spoonfuls of thin soup daily for the last few weeks of his life. The second and third were women, who were similarly starved for the last periods of their existence. In these three patients there was observable, during this period, a gradual lowering of the temperature, which, in the first instance, fell to 95° Fahr., and in the other two to 84.2°. These patients, during the last days of their existence, presented very similar disturbances of the intellect. Their physiognomy had a striking expression of studied satisfaction and dulness. The first patient would play with morsels of bread, and hide them under his pillow; then he fell for hours in a state of profound dulness. He was several times detected in the act of onanism. The patient, when roused from torpor, was constantly smiling in stupid fashion. The woman, when she was awake, had also an expression of great beatitude; she whistled, moved her fingers in rhythmical time, burst into loud laughter, or would remain for a long time together with her eyes fixed as in ecstasy. Larrey observed similar phenomena in individuals dying from the slow effects of cold.

SUBCUTANEOUS INJECTIONS OF ERGOTIN FOR THE VARICOSE VEINS OF PREGNANT WOMEN.—At a meeting of the Obstetrical Society of Berlin, in April, 1873,

Dr. Rugge related a case where he had obtained marked results from the use of ergotin. A woman, 36 years of age, who had suffered exceedingly, during a previous pregnancy, from varices, came under his care in the eighth month of pregnancy, suffering from her previous trouble. The veins of the left leg and thigh were enlarged, dilated, and tortuous.

Injections were made subcutaneously with from one to two grains of ergotin, and repeated every few days. The action was very apparent after the first injections, and after the seventh, the varices had almost disappeared. The right extremity was not affected.

There was some pain and infiltration following each insertion of the instrument, but no abscess occurred. The ergotin had no influence in provoking labor-pains.—*Berl. Klin. Woch.*, 44, 1873.

EXTIRPATION OF THE LARYNX WITH THE EPIGLOTTIS.—*The British Med. Jour.* of January 31st says that Professor Billroth, of Vienna, recently performed the operation of removing the larynx and epiglottis, a proceeding which had never before been attempted in the human subject, though Czerny had shown, in 1870, by careful experiments, that it was anatomically and physiologically practicable. The patient was a strong man, about forty years of age, the subject of cancerous growth in the larynx, which had repeatedly, after putting him in danger of death by suffocation, been removed by Dr. Störk with the aid of the laryngoscope. In the beginning of November the new growths extended so far into the interior of the larynx that their removal was no longer possible. As, however, a part of the right vocal cord was present, Drs. Störk and Billroth hoped to preserve this, however imperfect; they therefore opened the larynx from the front, and, after removing the growths, applied a solution of perchloride of iron to the inner surface. The result of this operation, which was well borne by the patient, appeared, at first, to be very promising; but in the middle of December new growths were detected by the laryngoscope, and at the end of a month symptoms of aphasia appeared. On December 30th, Drs. Billroth and Störk decided that the whole larynx was so full of malignant growths that it would be useless to repeat the operation of dividing it and clearing them out; and there was no longer a possibility of preserving the vocal cord. The entire larynx was therefore removed. The patient bore the operation very well. He breathed freely through the trachea in which a tube was inserted; the fever was slight, and of short duration; and on the 9th of January the wound was healing favorably. On the 24th the man was reported to be able to eat and drink, and to sit up several hours daily.

RETENTION CYSTS OF THE FEMALE URETHRA, AND THEIR RELATION TO THE FORMATION OF CARUNCLES.—Englisch, of Vienna, has frequently found at the post mortem examination of female infants, that cysts of the urethra have caused retention of urine, which has been accompanied by dilatation of the bladder, ureters, and pelves of the kidneys, and in some instances, atrophy of the kidney-tissue from pressure. These cysts are uniformly found in the neighborhood of the external orifice, and seem to be produced by the retained secretion in Littre's glands, which have their seat at this point.

If only a single such cyst exist, it presents a greater barrier to the flow of urine than several, because it gives a greater curve to the urethra, and because the mucous membrane often forms folds over the cyst. Epithelium is found in the interior, and it is claimed that the cysts formed in this way can always be dis-

tinguished from those that are produced by mere depressions in the mucous membrane, since the wall of the gland or membrana propria can always be distinguished in the former case; on the surface of this wall papillary outgrowths rise, and their extent varies with the size of the cyst.

Usually the cysts do not persist for a long time, but collapse, leaving depressions, in which the urine collects and decomposes, giving rise to the most troublesome irritation of the urethra.

After the lapse of time, and generally when puberty approaches, the capillary growths in these depressions give rise to the caruncles of the urethra. Dr. Englisch has collected thirty-five cases of this affection. The fact that they are met with so frequently about the time of puberty would point, he believes, to the chronic hyperemia of menstruation as a cause, though pregnancy had a similar influence in a smaller number of cases.

Though there is usually no difficulty about the diagnosis; still, in some instances, as for example when they lie deep in the urethra, the symptoms may simulate stone in the bladder. If the sound in the urethra fails to detect them, the passage may be dilated, which is easily done by the dressing forceps, and then these bodies will be readily detected. When the disease is deep-seated, and cannot be reached by ordinary caustics, the author recommends dividing the urethro-vaginal septum. By this means the application of reagents can be thorough, and in most cases a cure will be effected.—*Med. Jahrb.*, iv., 1873.

AMYL COLLOID IN SHINGLES.—Dr. Herbert Morgan writes to the *British Med. Jour.* that he is anxious to direct attention to the great efficacy of amyl colloid in removing the pain attendant upon shingles, which, as is well known, is out of proportion to the appearance of the eruption, and is often the cause of sleepless nights and great general discomfort. As far as his experience goes, no drug applied externally, or given by the mouth can be compared with the soothing effects of the amyl colloid painted for three or four coats round the clusters of the eruption. It may be applied as soon as the pain sets in, and continued twice daily as long as required; but it must not be applied on the eruption. In severe cases the addition of three or four grains of morphine to each drachm of the colloid will be found advantageous.

REPORTS OF PRACTICE AND PECULIARITIES IN TREATMENT.

STRUMOUS DISEASE OF TARSAL BONES.

This is a condition not infrequently met in general practice, and the little patients seen well illustrated the leading features of the disease. The term strumous is used in its common acceptation. It is probable that the child, as is ordinarily the case, as soon as she began to walk, sprained the ligaments concerned in the tarsal articulations, and developed a low grade of inflammatory action. This occurring in a strumous habit, went on, the bones themselves expanded, but there was neither caries nor necrosis.

There was apparently a thickening and spreading out of all the tissues, entering into the composition of the tarsus, and a consequent general enlargement. The ankle-joint was not involved. Local treatment, non-

irritating. Perforated lint, covered with simple cerate, and retained by a light bandage, was all the local application being made. The child was being saved by directing attention to the general constitutional condition. Good nourishment was a prime factor in the treatment. This, combined with such tonic remedies as seemed to be indicated, had already reduced the swelling of the foot fully one-third, and caused a manifest general improvement.

FRACTURE OF HUMERUS AND RADIUS.

There were some features of interest in a case of this order. The humerus had been fractured at the surgical neck, and the radius had suffered from Colles' fracture.

After the middle period of life, falls or blows received upon the lower extremity of the humerus and femur will produce fracture at the neck of either bone; while, as a rule, it is the reverse of this in the forearm and leg, where such violence is more apt to produce fractures at the lower extremity of radius and tibia.

The fracture at the neck of the humerus was oblique. It was said by the visiting surgeon, that in four out of five cases of oblique fracture of the surgical neck of humerus, union would take place without impairment of motion of the joint, but with a certain deformity, namely, the lower fragment would ride forwards and upwards. In this case the deformity was present, but shortening could not be detected by mensurement. The deformity is believed to be almost inevitable, for the reason that extension and counter-extension cannot be applied without producing so much pressure upon the axillary plexus that it cannot be borne.

FRACTURE OF TIBIA.

The fracture was at the junction of the middle and lower third, and was the result of muscular action. It had been in plaster dressings for about four weeks, and now upon removing the apparatus, pretty firm fibrous adhesion was found.

A single suggestion, made by the visiting surgeon while the limb was undergoing the manipulation necessary to determine whether union had taken place or not, was of interest. He remarked that there need be no hesitation in moving the limb somewhat freely, from the fact that motion, when the fracture is in this condition, does not necessitate any evil results (as was formerly supposed, and has been testified to in court), if properly made. A slight bending motion given to the soft structure does no harm; but a sliding motion to and fro will prevent union.

FRACTURE OF THE PATELLA.

When inflammatory action has subsided, plaster-of-Paris splint, with the limb in a straight position, is a common dressing used in this hospital. Inasmuch as the union will be ligamentous, one thing is regarded by the visiting surgeons as being essential to the proper management of this fracture, namely, an early removal of the splint, perhaps at the end of the fourth week, and resort to passive motion. In practising passive motion, the rule observed is always to hold the upper fragment, and then give slight motion to the joint, and gradually increase it.

DELIRIUM TREMENS.

The great demand of nature in these cases is rest. It is believed by one of the visiting physicians that the most beneficial rest which can be obtained is that produced by muscular fatigue. More food and less medicine, and let the patient tramp it out.

Repeated trials of digitalis in this hospital has not established it as a method of treatment.

Correspondence.

BRIEF REMARKS ON THE

FIRST PART OF MEDICAL AND SURGICAL HISTORY OF THE WAR.

By EZRA M. HUNT, M.D.,

METUCHEN, N. J.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Part first of the "Medical and Surgical History of the War" has now been long enough before the profession for us to begin to estimate its value as a contribution to medical and surgical science. One cannot refer to its maps, and in many instances its graphic descriptions of battles, as related to the care and disposal of sick and wounded, without obtaining valuable knowledge as to the war itself; but these incidental interests are quickly suspended by that which attaches to it as a clinical, medical, and surgical history. Our profession was fortunate in having, from the first, at the head of the Medical Department, those who had heroic love of medicine as a science, and who therefore, as by instinct, early commenced to look for improvement of professional knowledge through the materials and opportunities furnished by the exigencies of war. Our present Surgeon-General was prompt and active in extending plans already initiated, and in adding facilities for securing and classifying results. He was especially fortunate in securing such assistants and collaborators as gave practical and enthusiastic efficiency to the effort.

Not to undervalue the aid of Crane, Brinton, Woodhull, and others, we cannot be deemed invidious in singling out the names of Woodward and Otis as those to whom we owe the largest debt of gratitude.

The one was artist as well as physician, and from the first in charge of the medical records, and the other not less a patient plodder after accuracy in whatever he undertakes. These were ably aided by superiors in office and assistants in execution, and now place before us two volumes, ponderous in size, but so full of available knowledge as to be not only medical and surgical records of the war, but encyclopedias for the profession. Early attention was given to some record and to the formation of an Army Medical Museum; but there was much lack of precise clinical statement as to field service until in January, 1864, a compact register was furnished, and medical officers devoted themselves with energy to the classification of facts and material already secured, and to the easier and prompter report of cases as they occurred.

The perfecting and extending the plan of the Army Medical Museum, and the circular of June 24th, 1864, show the pains used to secure reliable information, illustrated and tested by morbid specimens. Secretary Stanton, Surgeon-General Barnes, and the other officers in charge, comprehended the magnitude and importance of the work, and with enthusiasm and accuracy subjected to examination, classification, and illustration the immense material coming at their call within their disposal. They succeeded in stirring the zeal of all the best medical and surgical force in the service, and even at length availed themselves of all that was valuable in the less extended records of the Confederate forces. We thus have volumes far surpassing in importance and interest the French and English records of the Crimean War, and a book which takes the lead of all other medical and surgical army records. It at

once is accepted as the grand pioneer of all national contributions to our science. It has occasion to be hailed by our physicians and surgeons as at once a recognition and exaltation of our profession in its intimate relations to patriotism and heroic defence of nationality.

It is indeed a successful endeavor to make the Medical and Surgical History of the War a contribution to science, a monument of the self-sacrificing zeal and professional ability of the volunteer and regular medical staff, and of the liberal provision of our government for the sick and wounded.

To review to any adequate extent would involve a volume rather than an essay, and we shall only attempt to notice some of its salient points and to estimate the relative importance of its contents.

The classification of diseases is based upon that of Dr. Farr; but some modifications were made, the propriety of which has been endorsed by the nomenclature of the Royal College of Physicians of London, 1869. The profession is well aware that there is still much defect in the nomenclature of disease, which can only be remedied by the increasing accuracy of knowledge as to its causes. We should not be perfectly clear in transferring Tonsillitis to Diseases of the Digestive Organs, and it has always seemed to us quite defective to make two classes of Constitutional Disease, placing as diathetic, or "predisposition to some disease rather than others," rheumatism, cancer, and the like, all in one class, and then making of Tubercular Disease a separate order.

But practically it was perhaps best to conform to the former nosology, with only such improvements as involved but slight modification. The use of English designations, instead of the "Latin version," is more convenient. By the separation of the Records of Departments and of Hospitals, and of the White from the Colored Records, we are able to make important comparisons. The supplement to the tables of the third fiscal year (p. 459) is also a valuable addition.

The regret is constantly experienced that we do not have meteorological records, so as to appreciate the relation of temperature, moisture, etc. For a period of over five years, in a mean strength of white troops of 468,275, the record in all is that of 5,825,480 cases of disease, of which only 7,187 are unclassified, and 166,623 deaths, of which 449 are unclassified. Allowing for all sources of error, yet an examination of the details of the report will, we think, convince any one that no more accurate series of statistics has ever been presented to the medical statistician. In addition, among colored troops we have, in a total mean strength of 63,645, 629,354 cases of sickness and 29,004 deaths. Of the most common zymotic diseases of the white troops, the following is, for our purpose, a sufficiently accurate statement of those in which the deaths exceeded 1,000:

There were of—

Typhoid fever.....	27,056 deaths.
Typho-malarial fever.....	4,059 "
Remittent fever.....	3,853 "
Congestive intermittent fever..	3,370 "
Acute diarrhoea.....	2,923 "
Chronic diarrhoea.....	27,588 "
Acute dysentery.....	4,084 "
Chronic dysentery.....	3,229 "
Erysipelas.....	1,860 "
Small-pox and varioloid.....	4,717 "
Measles.....	4,246 "

The proportionate number of deaths to cases was large in typhoid fever, chronic diarrhoea, and measles. In the latter one out of 16 died

Consumption is reported as having 5,286 deaths out of 13,499 cases; but no doubt many of these latter were sent home to die, and so lost sight of on the record.

The low number of nervous or cerebro-spinal diseases is quite noticeable.

Of apoplexy we have but 1,045 cases and 790 deaths. Of paralysis 2,837 cases and 231 deaths. Of sunstroke, 6,617 cases and 216 deaths.

Of valvular disease of the heart, the report is 3,778 cases and 610 deaths. Our experience taught us that many cases reported as organic were only functional. Of inflammation of bowels the report is 5,702 cases and 940 deaths. Hemorrhage from the lungs reports 209 deaths out of 5,745 cases, and inflammation of lungs, 14,738 deaths out of 61,202 cases.

Zymotic diseases furnish us in all 3,285,366 cases and 92,150 deaths. Diathetic diseases, 288,287 cases and 1,226 deaths of order 1st.

	Cases.	Deaths.
Tubercular diseases.....	19,830	5,418
Diseases of nervous system....	170,132	4,342
" circulating organs...	25,106	1,658
" respiratory "	448,923	17,902
" digestive "	563,239	4,146
" urinary and genital organs.....	29,875	430

All wounds, accidents, and injuries sum up 343,954 cases and 36,688 deaths.

This would leave all cases of disease 5,481,526, and of deaths from disease 129,935.

Our general ideas of war give prominence to surgery, but we thus see how much is purely medical. The additional 629,354 cases of disease and 29,004 deaths among colored troops do not materially modify these proportions.

The medical history, as contained in the first volume, is a valuable and well-selected record as given by various medical directors and other medical officers. While amid these necessary details there is much that is merely historical and incidental, yet many of them are full of valuable information as to localities and outbreaks of disease and topographical causes, as well as in reference to treatment.

We might easily designate some of these, which, from their condensation of style and clinical finish, must ever stand as models of army medical report. It is plain that the army medical corps was inspired with a professional as well as patriotic zeal, and that in most cases much pains has been taken to secure accuracy of medical and surgical information.

Both from statistics and from frequent references to reports, the large fatality of measles is especially noticeable, reference being also made to the fact that many who were reported as recovered afterward died or were discharged from lung complications. I am at a loss to account for the severity of the army epidemics of this disease, and that, too, where circumstances were favorable to treatment. We are again impressed that exposure and changes of temperature are much more dangerous in this than in small-pox and scarlet fever, and with the great influence of climatic and telluric condition in many cases.

The number of recoveries from lung wounds, in which blood was expectorated, seems to show that this class of injuries is not so critical as they have been regarded.

The subject of fevers as here presented excites much inquiry; but we await with great interest another volume, when Dr. Woodward will have opportunity to discuss with his known ability this whole subject, and to show the relations which these different types bore

to each other; to point out their line of diagnosis and methods of treatment. Impure water oftener than any other cause is recognized as inducing large sickness and mortality.

The use of chloroform was very universal in surgical cases, and its safety as used on the field and in hospitals does not make it so dangerous as it is coming to be estimated in home practice. Have we not in this regard occasion to study complicating accidents rather than to limit its use?

The whole of the medical volume is so necessarily introductory that it is only when the second shall appear that we can come to appreciate the bearing of the whole as a contribution to practical medicine. It is, however, so far complete as an introduction, that Dr. Otis is able, in the surgical department, after a detail of casualties of battle, to enter at once upon a classification of injuries, and upon a consideration of them, such as will be presented as to medical cases hereafter.

The second part of the work is already therefore full of practical interest to all students of surgery.

The brilliant success of Dr. Woodward in microphotography enables us to realize the objective teaching of the Army Medical Museum; and with a liberality worthy of all praise, by the Surgeon-General's direction six quarto volumes of photographs of cases, which have been formally examined, have been sent to the principal medical colleges and learned societies of the country. The Museum has also, besides its specimens, fourteen quarto volumes of contributed photographs. As soldiers have visited Washington they generally have found their way to the Army Museum, and by personal inspection, by correspondence, and by the co-operation of the Pension Bureau, cases of interest have been re-examined with much care.

Circular No. 6 prospectively assured us that the work would be sedulously and faithfully done, and the volume is up to expectations.

Of this volume nearly one-half of the regional portion is occupied with wounds and injuries of the head.

In the 282 cases of incised wounds of the scalp, we have the small mortality of 6, so far as known. We think, with Dr. Otis, that the danger of sutures and wounds of the scalp has been over-estimated. The lips of the wound, if at all extensive, is less apt to be inverted. The sutures need not be drawn very tightly. They must not be left too long, and free discharge must be allowed.

In incised fractures of the scalp, out of the eleven who had fragments of bone removed, only one died, while the general fatality was over 20 per cent. We have before this had the view that many cases of skull injury prove fatal because of absence of opening in the skull, and this seems to illustrate that view.

The case of O'Hare, as reported by A. P. Clark, 6th New York Cavalry, is so remarkable, we should like more clinical information. His cut extended from near the outer angle of the eye across the temporal region, nearly five inches, and nearly two drams of brain escaped.

There was "much cerebral disturbance," but nine days after he returned to duty. In 1864 he was a blacksmith at the headquarters of the Army of the Potomac, and is not on the pension lists.

In other cases we have the evidence of the greater fatality of lateral and posterior injuries.

Punctured fracture of the cranium proved very fatal, as out of the six five died, and one was permanently disabled.

Erysipelas as a sequel of gunshot wounds of the scalp was rare.

Epilepsy was a not infrequent result of head injuries.

Such cases as that of Bemis (p. 162), Lieutenant Burd (p. 180), Patrick Hughes (p. 206), etc., show us the wonderful possibilities of life amid the severest forms of skull and brain lesion.

The result of trephining after gunshot fractures of the skull are collected and detailed with great care from p. 261 to p. 295, and are more satisfactory than seems to us claimed, p. 320. The case p. 316 is interesting in its bearing on epilepsy and its relief. The recapitulation and general observations upon this large number of head injuries will be most valuable for future reference. In 175 cases of extraction of missiles penetrating the cranium, 89 were known to have recovered, and 83 to have died. Tables VII. and VIII., pp. 308 and 309, are worthy of careful study and analysis.

The recoveries from eye-injuries were frequently than could be expected in military surgery.

Some of the plastic operations are of much interest, both as to method, ingenuity, and success.

Out of the 75 cases of ligation of the common carotid, we find the large mortality of about 58 cases. The case of recovery after ligation of internal jugular vein (p. 397), is one of much interest; so also is that reported in p. 422. The former case is spoken of at p. 422 as fatal. Among the wounds and injuries of the neck, amounting to over 5,000, the small number of deaths by hemorrhage is very noticeable.

The large number of chest wounds, of almost every description, and the care with which they are considered, add much to the material value of this volume.

Many cases are reported of recovery after penetration of both lungs by gunshot missiles. In some of these the proof, however, as to the wounding of internal tissue is feebly circumstantial. The plan of hermetically sealing the external chest wound, thus excluding the outer entrance of air into the pleural cavity, or the lung, as carried out by Surgeon Howard and others (p. 499), has much in theory and practice to commend it. Although not entirely new, it is thus brought prominently to notice. It is a plan not applicable to all cases, but that dyspnea and some other symptoms were promptly relieved thereby is undeniable. Pages 519-522 are very interesting as to this treatment.

The statistics of pericardiac and cardiac lesions show the possibilities of life, and of occasional recovery under such injuries.

The record affords no instance of a wounding of the thoracic duct, and the same was the case as to the Crimean War.

The chapter on ligation of the chief arteries about the chest is full of interesting detail.

Case 15, on p. 587, not only shows how the lung tissue will tolerate and provide for a foreign body, but also the kind of transformation which the lung undergoes and the occasion of chalky deposit. Tubercle itself sometimes has a similar history. The case p. 596 is remarkable throughout. The frequency of pneumonia after wounds of the lung is not so general as Erichsen has stated it. In fact, we cannot rise from the study of this great collection of lung cases without feeling that prompt measures and proper remedies accomplish more with the lungs than with any other of what are called the vital organs. Our own experience greatly impressed us with this view. The plan for relieving pneumothorax, hydrothorax, hemothorax, etc., by a valvular opening (p. 627), allowing egress, but preventing ingress, seems theoretically valuable, and is worthy of more extended trial.

Hæmoptysis is spoken of as of doubtful value as a

sign of lung wound. It is true that it may occur from concussion or other causes, but generally where there is a wound of the chest wall, and hæmoptysis following, we should not, with Chisolm, speak of spitting of blood as "a very deceptive diagnostic sign."

The extract from the Confederate Surgical Manual (p. 644) as to venesection in chest wounds and its inapplicability except for "general plethora or local visceral engorgements," cannot be too carefully regarded. Under the head of treatment we draw attention to three most valuable remarks. Opium is so often required that it merits the first place, and pure opium in substance, as Dr. Squibb remarks, is more reliable than any preparation. As to calomel, Mr. Wharton has ably directed attention to the fact that "sufficient importance has not been paid, in the treatment of these lesions, to the necessity of maintaining the blood in such a condition as to favor its coagulability, on which the natural reparative process depends. Great caution should therefore be exercised in administering any drug likely to appreciably diminish the normal proportion of fibrin."

On veratrum viride, which Clark says can kill splendidly, Dr. Otis well remarks: "I believe that any good results to be obtained from it may be arrived at with greater certainty and safety by using antimonials combined with narcotics."

Part first of the surgical volume ends worthy of itself, and the last two pages are almost good enough for committal. There are many points and cases upon which we would have liked to enlarge did time permit.

Dr. Woodward and Dr. Otis, under the intelligent patronage of the Surgeon-General and Government, are doing a service of philanthropic not less than scientific merit.

We await with interest the other volumes, and doubt not they will worthily complete a record of lasting value to our profession and to humanity.

THE HISTORY OF THE OPHTHALMOSCOPE AS AN OPTOMETER.

REPLY TO DR. EDW. G. LORING'S COMMUNICATION.

BY H. KNAPP, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I am anxious to acknowledge the correctness of an historical information with which, in the above cited communication, Dr. E. G. Loring honored my paper on ophthalmoscopic optometry, read before the New York County Medical Society, and published in your journal on Jan. 15, 1874. I had been under the impression that I was the first who described (at the International Congress of Oculists at Paris, in August, 1867) the method of measuring, by means of the ophthalmoscope, elevations and depressions in the background of the eye; but by Dr. Loring's quotation, the correctness of which I have verified, I see that Dr. Mauthner described the same method eight months previously in the *Austrian Journal of Practical Medicine*, on Dec. 28, 1866. Dr. Loring did not mention this fact in the discussion on my paper, but merely stated that a part of Mauthner's treatise of 1868, upon which my opinion was based, had appeared in 1867. I replied that I did not think this was a sufficient evidence of my having been anticipated by Dr. Mauthner, nor had any one, at the Congress in Paris, informed

me of such an anticipation. On the contrary, I had been complimented on the elegance and novelty of the method of which, I may be allowed here to add, Sichel père said, after the session, that it could be used to delineate an "*orographie du fond de l'œil*" in the living subject. The optical deduction which I gave at that time, and which is published in the Transactions of the meeting, differs from that which Mauthner used, and which he took from Helmholtz's general discussion of the dioptries of the eye. I make these statements to show that I arrived at the method independently, and, though mistaken, acted in good faith when I said that I had described the method first. The quoted article in the Austrian Journal decides the question of priority in favor of Mauthner.

Apart from this, there is another incorrect assertion in my paper. I had been hasty in saying that a case of hyperopia $\frac{1}{2}$ in one eye and $\frac{1}{3}$ in the other—which had come under my notice and was cited for the sake of illustration—represented the highest degree of hyperopia ever observed in eyes possessed of their crystalline lenses. I see, from the quotation in Dr. Loring's communication, that a few cases are on record which show still higher degrees.

I am under obligation to Dr. Loring for these two of his statements, but have no other concession to make. That ametropia can be determined with the ophthalmoscope is mentioned in the earliest as well as in the most recent literature on ophthalmoscopy; in fact, the method of examination in the erect image must suggest it to everybody. I therefore cited no authors on this subject, and certainly did not myself presume of claiming any merit in it, nor can such a presumption be found in what I have said or written. As a useful method in practice, however, this mode of determination has been more generally cultivated during the last years only. That Dr. Loring was one of its promoters I have acknowledged in my paper, and I gladly repeat it. Should he, however, even at the present day, visit the different ophthalmic clinics, both in this country and in Europe, he would convince himself that the method of determining, with the ophthalmoscope, the optical condition of the eye—for which I have ventured to propose the expression, "ophthalmoscopic optometry"—is still little practised, and he would, I trust, exonerate me for introducing it to an audience of physicians in general practice as having, in addition to its usefulness, some claims on their attention on account of its comparative novelty.

TREATMENT OF SORE NIPPLES.

By EPHRAIM CUTTER, M.D.,

WOBURN, MASS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your issue of September 15, 1873, I noticed some excellent remarks upon the above subject by Prof. Fordyce Barker, and I write to add a contribution which I think deserves some attention, viz.: that by removing the mechanical conditions that help keep up the disease, you are giving the systemic and topical medicines a better chance of completing a cure of this apparently trivial but common and sometimes very painful affection.

Some years ago, when my wife was troubled with sore nipples, the idea occurred to me whether the deranged physical conditions of an inflamed and ulcerated nipple did not aggravate it.

I. The nipple projects naturally horizontally forwards, standing prominently upon the most elevated

point of the convex surface of the breast. Of course it impinges upon the concave surface of the dress enclosing the chest—generally rather stiff, unyielding corsets—and the nipple is driven inwardly into the convexity of the breast. If the mammary gland is soft and inactive no appreciable trouble results except the flattening of the nipple, which sometimes becomes permanent. But during lactation the gland is generally distended and hard, so that the sore nipple is, as it were, crushed against it. This crushed condition must interfere with the circulation and interfere with the healing process.

II. This flattening of the nipple causes a deep re-entrant angle to be formed at the base of the nipple—where the sores are often found—by the sides of the nipple and the breast. This fold keeps out the air and puts the skin involved into the condition of a mucous membrane. The secretions are retained, the epithelium is softened, and after a time the nipple becomes illy fitted to bear the grip of the alveolar processes of the infant.

III. Allow a looseness of dress, still the nipple, generally more erectile the more it is inflamed, will be touched by the lateral movements of the dress, and consequently kept moving from side to side. In this case the physical conditions are analogous to those of fissure on the knuckle of a finger—hard to cure because always moving.

Now remove the flattening—the moist condition and the motion of the diseased nipple—and you so restore the normal condition that often, without any other assistance, it will recover. Or, to put it differently, give it *rest* and *ventilation*, and it will get well of itself.

The problem is, to have the nipple, during the intervals of suckling, protected from the pressure of the clothes and freely open to the circulation of *dry* air. Dryness is a normal condition of the skin, as moisture is of the mucous membrane. To accomplish this, disks of cork about $2\frac{1}{2}$ inches in diameter and $1\frac{1}{2}$ in thickness were selected. A central opening was made, and then enlarged by filing with a common rat-tailed file until the opening on one side was within half an inch of the edge, and the opening on the opposite side was about one inch in diameter. With sand-paper the surfaces are smoothed and rounded. A common two-gallon milk-can cork suffices. Thus you obtain a conical excavation within the cork which will cover the nipple, keep off the clothes, and allow ventilation. The lightness of the cork, its being a non-conductor of heat, and its facility of manipulation, entitle it to a first place for this purpose. At first sight it might appear that the cork would absorb the secretions, so as to become offensive. I have not found it so. It is easily cleaned by pouring on boiling water.

With this device remedies may be employed. I have found an ointment of a grain of sulph. morphia to a drachm of lard an excellent application after suckling, to be removed if not absorbed before suckling.

It is but justice to add that Kent's nipple-shield is something on this principle. But his device is of glass, and fits tight to the nipple. It does not present such broad surfaces for impinging upon the breast or clothing, nor the lateral openings through the sides which may be made through the cork.

In conclusion, perhaps I may say that the device just described relieved my partner's pain, and a cure soon followed. This experience has been repeated with other women's sore nipples so frequently, that the writer feels justified in sending this paper to THE MEDICAL RECORD.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, April 1, 1874.

CONSULTATIONS IN THE COUNTRY.

NOTWITHSTANDING there are a great many rules laid down in the code for the government of consultations, there are still some points in the unwritten law of medicine, in regard to them, which are either not understood or are purposely ignored by very many practitioners. For a thoughtless or ill-disposed person there is always an opportunity, which, if ignorantly or meanly seized during a consultation, can be made to be injurious, nay, ruinous, to the regular attendant. The dangers are indeed so great that, in order to guard against them, the consulting gentleman has his actions hemmed in by all sorts of restrictions, and is always expected to strain a point and conscientiously use every honorable means to strengthen and maintain that confidence and esteem which should always exist between the family physician and patient. There are different ways of doing this, which must suggest themselves to every consulting practitioner, and which must be modified by circumstances, surroundings, and conditions.

The very office of consulting physician generally carries with it such advantages that almost always the claim for protection and support must come from the gentleman in direct charge of the case. The necessity for a consultation generally proves the existence of a desperate case, one in which extra counsel is required. The consulting physician is either chosen by the patient, the physician, or both, and for the time being is looked upon, by the friends of the patient at least, as an adviser whose opinions concerning the particular case in question are of a peculiar value. We maintain that the consulting physician, while he admits to himself the necessity for his services, and accepts the choice as a compliment to his skill and abilities, should be exceedingly particular to discharge his delicate and responsible duties to the satisfaction of the patient's friends, and especially to the patient's physician.

Consultations are always useful, and all other things

being equal, cannot be held too frequently. They are not only a great relief to the minds of our patients and their friends, not only a source of satisfaction to ourselves, but in the main tend to establish a confidence in the healing art, a respect for medicine as a science, a more thorough appreciation of its resources, and a conviction in the minds of our patients that we as a class of professional men are anxious and willing to do everything which a combination of skill and experience can effect. For either party to the consultation to attempt to make capital of the circumstance, is not only unprofessional, but unbecoming that spirit which seeks the welfare of suffering humanity in the light of a strict and conscientious interpretation of scientific truths. Under these circumstances individual considerations, and self-glorifications, should be lost in the desire to elevate the profession as a whole. We do not believe that anything tends to destroy this confidence more effectually than an attempt on the part of either member of the consultation to prove to non-professionals the possession of a superior knowledge and skill.

Despite all our efforts, there must be some wrongs inflicted, some misunderstandings initiated, some unwarrantable estimates of relative skill made by our patrons. All cannot be expected to be equally informed, skillful, or discriminative; we all differ in these respects, one with another. It, however, should always be the endeavor of the new-comer into a case, the one whose aid and counsel is sought, to reduce the chances of an over-estimate of his abilities to the minimum. Taking a strictly honorable view of such relations as should exist between the consulting and family practitioner, this should always be the case. A consulting physician or surgeon is called in to aid both the family attendant and the patient, and nothing more. He does not sacrifice any of his interests by a manly course of action to both parties, and as his attendance with a given case is expected to cease with the consultation, there is no temptation for him to aspire for any further or future control of the patient; at least there should be none.

Cases not unfrequently arise in which peculiar circumstances should alter the usual relations of practitioners to each other, for instance, where special operations are to be performed, in which a special experience is required. The one who has such skill should give the patient the benefit of it, and no considerations of professional pride, and no liberal interpretation of the code should interfere. It would be worse than criminal for any practitioner, merely bent on maintaining a hold upon his patient, to insist upon performing an operation, which at best he could do in a very bungling manner, in the presence of the other party to the consultation, who may be an expert. But in these cases common courtesy generally adjusts all such difficulties, and when the professional positions of each are honorably and properly balanced, no advantage can be taken by one over the other.

But we have been alluding to misunderstandings which may arise in the best regulated consultations, and for which neither party can be blamed. There are other matters connected with these professional intercourses which cannot be included in such a category, but which are open and defiant violations of ordinary professional decency. We refer to a practice which of late has come quite into vogue, and which, in the magnitude of the evil influences which it may exert, will probably outshine all the rest. It is well known that there are certain customs which must regulate consultations at a distance, that the emergency of a given case, and many other considerations may make it impossible for two consultants to meet punctually. All allow of such possibilities, and none are willing that the patient should lose the benefit of the opinions of either member of the council on that account. Each physician can examine the patient separately, and give an opinion separately, without interfering with the other, and giving the patient every benefit. Every practitioner knows how this can be done, without making it necessary to go into detail.

Strange as it may seem, however, we have yet to learn that there are exceptions to these rules, to be made wholly in favor of metropolitan practitioners who may be summoned by telegraphic despatch to see patients in distant parts of the country. Every one knows how natural it is for families who can afford to pay well for services, to use every means in their power to save the life of one of their members, and that very often they act independently of their family medical adviser in the matter. The custom of sending for practitioners from a distance has become an established one, and the abuses connected therewith are by no means few and unimportant. When a message is sent by one physician to another, the case is plain enough; but when the request is made by the friends of the patient, there is a good deal of room for doubt as to the regularity of the proceeding. Under the circumstances there is not much time for explanation, and the first train is taken for the point of destination. Not unfrequently the family attendant is in readiness to meet his metropolitan brother in consultation, and then the case is still a plain and uncomplicated one. If, however, the metropolitan is hurried to the house to see the patient alone, prescribes, and hurries back to the depot, the case, in the matter of professional courtesy, is no longer a simple one, especially if a medical gentleman is already in attendance upon the case. He may be nothing more than a country practitioner, it is true; but still, even country practitioners have been taught to believe that they have some rights, and are apt to feel quite ticklish when such rights are impudently and unnecessarily assailed. If such cases were not constantly occurring we could hardly believe in their possibility, and would deem ourselves guilty of appealing to our imagination instead of facts. We have now in mind a case which occurred within a few miles of this city,

and to which a very prominent practitioner here was hastily summoned by the patient's friends. Not being able to respond, he sent his assistant, to whom was delegated the right to speak and act for him. The assistant makes the journey, arrives at the house of the patient, who was sick enough to create no doubt in his mind that another practitioner was in attendance. He asked no questions concerning the family physician, nor did he apparently care, and altered the whole plan of treatment, the importance of which was magnified by his fussiness and his gloomy prognostications. The regular attendant arrives subsequently, to use a mild expression, is astonished, and vainly imagines that there must have been some misapprehension on the part of the consulting physician; but all doubts are removed when, the subsequent day, the assistant sends a medical friend to watch with the patient, to see that there is no interference with the new treatment.

This is only one instance of many of a similar import that has come to our knowledge. If there can be any excuse for such proceedings we should like to know what it is. When a patient is under the care of a quack, the quack deserves to be entirely ignored; but when a respectable practitioner has charge of the case, the professional obligation of a second party is slightly altered. If not, there is no need of any honorable professional understanding among men, big or little. No one can believe that any medical man has a right to see such a case without ascertaining if there be any physician in attendance, and having ascertained such a fact he is, under the strongest possible obligation, to see the patient, if possible, only in the presence of such an attendant. If any peculiar circumstance prevents this, the opinion can be given under seal; but no direct alteration in the plan of treatment should, under the circumstance, be received in any other light than that of an insult. Any medical man who may be guilty of such a misdemeanor is liable to the most rigid discipline, and we hope that the parties injured will not be backward in preferring charges before the County Society. The larger the man, the greater his reputation, the better example for just punishment. Our astonishment that such unprofessional practices do actually exist is only equalled by our disgust for such as can lower their professional manhood to stoop to them.

RECEPTION HOSPITALS IN THE CITY.

WE have repeatedly pointed out the necessity for small reception hospitals in the different sections of the city, not only on account of their convenience and comparative cheapness, but because a small hospital is a much better place to treat the sick than a larger one. It is unnecessary to detail the reasons for these conclusions, as they are now sufficiently appreciated by the profession at large, and have been time and time again presented by the leading sanitarians throughout the civilized world. Now it would appear that a practical turn is about to be taken in the

proper direction. The governors of the New York Hospital have decided to open such an institution in Sixteenth street, and it is to be hoped that its success and the proof of its urgent need in one section of the city may induce them to open others in other sections. At present there are but two reception hospitals—one at the Park and the other at Harlem; and during the past year this former institution, with a capacity of only thirty-one beds, cared for thirty-five hundred cases. The latter did a work in equal proportion to the number of the population in its district. We want at least four more institutions scattered over the city, principally on the east and west sides. Cannot the Commissioners of Charities and Corrections also do something towards ministering to such necessities?

HOSPITAL APPOINTMENTS.

As an evidence of reform in hospital appointments, we are pleased to notice that the members of the House Staff of the Reception Hospitals, instead of being appointed by the Commissioners of Charities and Corrections, are now compelled to submit to an examination by a Medical Board before such appointments can be secured. This system has been inaugurated by Prof. F. H. Hamilton, the Surgeon-in-chief of the said Hospitals, and has been attended with the best of results. For a number of years the positions on the House Staff of Bellevue, of Charity, and other large Hospitals have been secured by such means only, and the young men who occupy these positions reflect credit upon the profession at large. There is no question that the plan is the best that can be adopted, and that it should extend to every hospital and dispensary throughout the land, to the police surgeons, to all positions of medical trust, and even to the visiting surgeons and physicians of all our public charities.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 10, 1873.

DR. E. L. KEYES, PRESIDENT, in the Chair.

DR. J. LEWIS SMITH presented a specimen of

DIPHTHERIA,

with the following history: T., aged three years, died after a sickness of about one week from diphtheria, which supervened upon measles. During the last four or five days of the disease the symptoms, namely, stridulous inspiration, depression of the sternum during inspiration, and lividity of the lips and tips of fingers, indicated extreme laryngo-tracheal obstruction. The fauces, which were inspected each day, were constantly swollen and injected, but without a pseudo-membrane. Five days before death the pulse was 164, respiration 28 per minute, and temperature $101\frac{1}{2}^{\circ}$; two days before death the pulse was 160, respiration 28, and temperature 104° .

The post-mortem examination embraced only the la-

rynx, trachea, and commencement of the bronchi. A continuous pseudo-membrane extended from the tip of the epiglottis downward over the mucous membrane as far as it could be traced in the dissection. It was thicker and firmer below than above, so that it probably extended into the smaller divisions of the bronchial tree. It was somewhat pultaceous on the under surface of the epiglottis and in the larynx, but it could not be readily separated from the mucous membrane; while in the trachea it was readily detached in a thick and firm layer. The mucous surface underneath presented a deep-red color, and was considerably thickened by hyperemia and infiltration.

It seems evident that the disease of which this child died was diphtheria, and not true croup, from the fact that the former was epidemic in the institution at the time, three children having diphtheritic inflammation of the eyelids in the same ward in which this patient was treated.

During an epidemic of diphtheria the specific inflammation is apt to attack those surfaces which are already inflamed or irritated, and in many patients it affects only such. Therefore if it attack a patient with scarlet fever, its seat is the fauces, and if, as in the present instance, one with measles, in which there is general inflammation of the air-passages, it ordinarily involves not only the fauces, but also the surface of the larynx, trachea, and bronchial tubes, being, therefore, from the extent and thickness of the pseudo-membrane, ordinarily fatal. The three children with diphtheritic conjunctivitis, alluded to above, were previously under treatment for inflammation of the eyelids.

It is important, both as regards prognosis and treatment, to determine in cases like the above, in which there is obstructed respiration but no pseudo-membrane on parts which are visible, whether the laryngo-tracheitis is catarrhal, with an unusual degree of infiltration, or pseudo-membranous. From my observation of these cases I do not doubt, if the dyspnea do not begin to abate by the second or third day under appropriate treatment, that we are contending with a pseudo-membrane.

This patient was treated with quinine, iron, and alcoholic stimulants internally. The quinine was administered in moderate doses; but in severe diphtheria and scarlet fever large or frequent doses of this agent are tolerated, and are sometimes apparently useful. When I entered on duty in the Asylum in the same epidemic, one of my colleagues was treating a patient of three and a half years, having severe scarlet fever and diphtheria, with two grains of quinine administered hourly, and though forty-eight grains had been given in twenty-four hours, the pulse was 156 per minute, and the temperature, $103\frac{1}{2}^{\circ}$, showing that there was not such reduction of pulse and temperature as ordinarily attends the employment of large doses of this agent. The patient recovered, the quantity of quinine administered daily being, however, reduced to twelve grains.

The local treatment in the case which I have related consisted in the application to the fauces, every three hours, of the following, which has given me better satisfaction than any other medicine for local treatment which I have employed:

B. Acidi Carbolicæ.....gtt. v.
Liq. Ferri Subsulphat.....3 ij.
Glycerine.....3 i.

M.

The brush was employed in preference to the probang, as it is less painful, and where there is a pseudo-membrane does not produce hemorrhage by its detachment.

The small room in which the child was treated was also filled, as far as possible, with steam. As steam or water softens the epidermis, so I believe that it softens and aids in the removal of the pseudo-membrane, which is mainly epithelial, more effectually than any other local measure. In each of the shallow pans from which the steam was generated, a small lump of quicklime was placed, so that the steam was charged with particles of lime, which were quite perceptible in the breath. If much lime be added, the water becomes too thick or syrupy, so as to diminish the evaporation, and therefore render the quantity of steam insufficient. The spray of lime-water, whatever may be its solvent effect, certainly renders the respiration in a close and hot room more tolerable, perhaps from its rapid absorption of carbonic acid.

INTUSSUSCEPTION.

This specimen shows an intussusception occurring in the ileum, about one foot above the ileo-cæcal valve. The child in whom it occurred was thirteen months old at the time of death. On the day before its death, its previous health having been good, it seemed ill, and vomited once or twice, but did not appear to be in pain. It had two evacuations from the bowels, of the usual appearance, in the latter part of the day. On the following morning it was unexpectedly in collapse, and died in about twenty-four hours from the commencement of its sickness.

At the post-mortem examination the head was not opened, and all the organs of the trunk were found normal, except the intussusception. The mass involved in the displacement measured two and a half inches in length, and was slightly crescentic. The mucous membrane immediately above and below it had the normal color and appearance, as did that of the external or incarcerated portion of the mass, while that of the incarcerated portion was deeply injected. Water poured into the intestine above the invagination was wholly arrested by it.

It was evident from the size of the intussusception, and the strangulation of the vessels in its interior, that it must have occurred sometime before death, probably the day previous, at the time of the vomiting, and that it could not have been reduced by the vernicular and peristaltic movements. It was apparently the cause of the collapse and death. This case, with others which I have reported, is interesting as showing that that form of intussusception which Rilleit and Barthez designated intussusception with symptoms, in contradistinction to the simple form, which occurs without symptoms, may take place in the small intestines of young infants, contrary to the opinion of these observers. In nearly all instances fatal intussusception in infants occurs in the large intestines, but the cases which I have reported establish the fact of an occasional exception. In a recent valuable paper on intussusception, D. Jonathan Hutchinson alludes to death by collapse as one of the modes of termination in cases of this displacement.

PERTUSSIS.

Male, aged 4 years, died in the seventh week, of pertussis. Was treated at first by quinine, and then by belladonna. The cough had been severe, but in the last week of his life was quite moderate. He also had diarrhoea during the last two weeks, accompanied by febrile movements, and due, as afterwards appeared from the post-mortem examination, to severe enterocolitis. In the few days immediately preceding his death he seemed slightly delirious, and the movements of his head were such that the physician in attendance

diagnosed meningitis. On the day before death the pupils responded to light, a few moist râles were observed in the chest, the respiration was accelerated, the pulse 160 per minute, and temperature 102½°.

Autopsy.—About one ounce of transparent serum flowed from the cranial cavity, evidently having escaped by transudation from the engorged vessels; venous congestion of brain and meninges; cranial sinuses engorged with blood, containing large, dark clots; numerous "blood points" on the incised surface of the brain; encephalon otherwise normal. Lungs: mucous membrane of larynx and trachea nearly normal, slightly vascular; both the upper lobes and anterior portions of the lower inflated to the utmost, and exsanguine, presenting the lesion of incipient vesicular emphysema; the alveoli in these portions are visible to the naked eye; right middle lobe and posterior and inferior portions of lower lobes collapsed, and allowing only slight expansion by insufflation; left auricle and both ventricles of the heart empty; right auricle distended with dark blood, and containing clots; entire mucous membrane of large intestine deeply injected and thickened, and that of the lower part of the ileum also hyperæmic, but in less degree and with little thickening. A few superficial ulcerations were observed upon the mucous membrane of the colon, and also at one point a thin film as of a pseudo-membrane.

The febrile movement in this case, which, in connection with the cerebral symptoms, was supposed to indicate meningitis, was, no doubt, due to the enterocolitis. The cerebral symptoms were attributable to the passive congestion of the meningeal and cerebral vessels, and the consequent serous transudation. In all cases of pertussis more or less cerebral congestion attends the paroxysms of coughing, but it is only when they are frequent and severe that intracranial serous effusion, like the oedema of the eyelids, is apt to occur. The greatest amount of cerebral and meningeal congestion and transudation occurs when eclampsia complicates the paroxysms, and such cases are apt to be fatal from coma, which this affection of the encephalon produces.

These specimens show what portions of the lungs experience most the pressure from the air confined within their alveoli during the paroxysms of pertussis, and from what portions the air is most withdrawn, so as to endanger or produce collapse. Emphysematous distention of both superior lobes, and of the anterior portions of the lower lobes, had occurred, proving the correctness of the theory that emphysema does in certain instances result from forcible expirations.

The comparative effects of quinine and belladonna as remedies for pertussis were observed in this case. My own experience with these agents, now in a considerable number of cases, without, however, any exact statistics of their effects, incline me still to prefer belladonna in ordinary cases, given twice daily in doses sufficiently large to produce its physiological effects. An abatement in the severity of the cough may be confidently expected when the belladonna has been employed a few days. Quinine is useful, in addition to external irritation, when there is febrile movement with accelerated respiration, due to bronchitis or broncho-pneumonia. If cerebral symptoms arise, as in the above case, bromide of potassium I have found more useful than any other remedy, administered alone or with iodide of potassium.

THE MEDICAL RECORD will have its leaves cut for the convenience of our readers.

Stated Meeting, Dec. 24, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

SEQUESTRUM IN AN UNUSUAL SITUATION.

Dr. Post presented, first, a sequestrum which had been removed from the thigh of a patient about 45 years of age, colored, and an inmate of Presbyterian Hospital. The specimen was interesting chiefly on account of the locality in which it occurred. The patient spoke vaguely of his preceding history, but about two years ago noticed a swelling at the upper part of the thigh, and about one year ago suppuration occurred at that point and matter was discharged. When he first saw the patient there was a sinus situated at the outer and upper portion of the thigh, near the middle, which extended upwards to near the trochanter; probably not more than two inches below the great trochanter, in which dead bone could be felt. Whether the great trochanter was implicated or not could not be determined. A long, free incision was made through the soft parts down to the bone, the finger introduced, and it was found that it penetrated a smooth, rounded opening at the outer and anterior part of the bone, and a loose portion of bone could then be felt. A strong pair of forceps was introduced, and the piece of dead bone removed without difficulty. There was an imperfectly formed involucrum, and the cloaca was sufficiently large to allow the sequestrum to be removed without further enlargement. A localized necrosis in that portion of the thigh-bone is not common, at least, and to him was something new.

VESICAL CALCULUS—LITHOTRITY—DEATH FROM NERVOUS PROSTRATION.

Dr. Post inquired whether any gentleman present had met with necrosis in that portion of the thigh from which his specimen had been removed.

The President, DR. MASON, replied, that he had not seen necrosis at that exact locality, but had seen it just above the trochanter, and involving the neck of the bone, and that he had heard of two more cases of a similar nature.

Dr. Post presented a second specimen, consisting of the fragments of a calculus. He was called, in the month of August, 1873, to visit a man, 62 years of age, who had suffered from symptoms of vesical irritation for the last two or three years, but had never been sounded. Some fragments of stone had been passed spontaneously, which had been collected. The patient was sounded with a lithotrite while under the influence of ether, and he was able to grasp a stone about three-fourths of an inch in diameter. The patient had expressed a strong desire, previous to the sounding, that nothing should be done in the way of crushing the stone at that time.

A scale of stone weighing about two grains came away with the instrument when it was withdrawn. A day or two subsequently the patient was again visited, and an attempt was made to crush without using ether. The patient, however, complained excessively while the manipulation was being performed, and the operation was deferred for a couple of days. At the end of two days the patient was etherized, the lithotrite introduced, and after a little effort the stone was firmly seized and crushed. Some fragments came away with the instrument, and others came away afterwards. The patient, after the operation, was left mainly in the care of the attending physician, but the doctor was called to see him in the night of the following day, and found that he was suffering from severe diarrhoea.

Since the operation the vesical irritation had rather

diminished. The diarrhoea had become uncontrollable, the rectum was very irritable, but another effort was made to check the discharges by administering ℥ x. Magendie's solution hypodermically. The diarrhoea became somewhat less, but the patient died before morning. Death was apparently caused by extreme nervous prostration and the irritable state of the bowels, in connection with the oppressive weather which occurred at that time. The death of the patient was not regarded as legitimate from the operation. The Doctor remarked that this was his first case of stone in the bladder which had terminated unfavorably while under his treatment.

The President, DR. MASON, then inquired whether there was any bloody urine passed, or whether there was any suppression of urine previous to death in Dr. Post's second case, and was answered in the negative.

GLIOMA-SARCOMA OF UPPER THIGH AND GLUTEAL REGION.

The PRESIDENT presented, first, a tumor which had been removed from the posterior portion of the thigh of a woman, 33 years of age, who had always enjoyed good health.

In August, 1872, she first noticed that her left leg and ankle were rather weak, and occasionally she would suffer considerable pain in the neighborhood of that ankle. The recurrence of pain continued in the neighborhood of the ankle and foot up to October, 1872, when, while in the act of sitting down, she felt a sharp pain in the posterior portion of the thigh, and then noticed, for the first time, the existence of a tumor situated about the middle of the posterior portion of the thigh, which when first discovered was about the size of her fist. This tumor gradually increased in size, and without any apparent detriment to her general health. When admitted to Roosevelt Hospital she presented a growth occupying the posterior portion of the left thigh, of ovoid shape, with a prolongation upwards. The tumor measured in its long diameter $9\frac{1}{2}$ inches, extending from the upper part of the popliteal space upwards to the gluteo-femoral fold. The thigh over the tumor measured $17\frac{1}{2}$ inches. The opposite thigh, in a corresponding locality, measured $14\frac{1}{2}$ inches in circumference. The calf of the limb affected was somewhat atrophied, measuring one inch less in circumference than the calf of the sound limb.

The tumor now gave her great inconvenience while sitting, and pressure from above downwards, or by passing the fingers along the sides of the tumor, would also cause pain. The tumor was freely movable in a lateral direction, but up and down it seemed to be attached. It had commenced growing somewhat rapidly, and had extended in rather an upward direction. On the 11th of December the tumor was removed. Upon cutting through the integuments and fasciata, the tumor was noticed to be covered with a thin layer of muscular fibres.

This being cut through, a dark-colored tumor was exposed, and it became apparent at once that it was connected with, or in some way involved, the sciatic nerve. Upon farther examination it was found that the nerve not only entered the tumor, but was spread completely over it, rendering it impossible to separate the growth from the nerve. The nerve was accordingly divided above and below the tumor, and the mass was then easily enucleated. Very little hemorrhage attended or followed the operation. The wound was dressed in the ordinary manner, using, however, only two sutures. Reaction was bad.

The patient was quite prostrated, and an hour or more passed before she rallied from the effects of the

ether and the operation. At 6 P.M. (3½ hours after) of the same day her general temperature was 98½°; that of the foot, 98½°. On the following day her general temperature in the morning was 100½°; foot, 99°. Evening, 102°; foot, 101½. Sensibility was absent from plantar surface of the foot and external surface of the leg, especially about the lower border. Sensibility absent from the posterior portion of the calf of the affected limb, but that is returning, and she can now feel in that locality. She is able to flex the leg upon the thigh, and the thigh upon the pelvis, and extend the leg. There is no motion of the toes, or flexion or extension of the ankle. The wound healed with great rapidity, without an unfavorable symptom, and the woman is now able to sit up, with the wound almost completely closed. No atrophy of the limb has occurred as yet. On the 21st of this month she experienced a slight twitching of the foot and toes, and a slight tingling sensation in the sole of the foot.

The tumor was placed in the hands of Dr. Francis Delafeld for microscopical examination, and he has furnished the following report:

"The tumor consists of a dense fibrous capsule enveloping soft hemorrhagic tissue. This tissue consists principally of small, round cells. The growth seems to have originated in the nerve-bundles, and apparently from the neurolemma of the nerve-fibres. It would therefore be called a glioma or gliosarcoma of the nerves." The third day after the operation the temperature of the foot became the same as that of the general system. The patient has since been discharged from the hospital, and at the time of her discharge was able to walk quite well, a bandage being so applied as to retain the foot at right angle with the leg.

ABSCESS OF BLADDER.

The second specimen presented by the President was a bladder with its hypertrophied prostate gland. The specimen presented some novel and interesting features as connected with diseases of the bladder and enlarged prostate. It was removed from a man 73 years of age, who was admitted to the Charity Hospital, August 14, 1873. There was nothing of special interest in the case until October 9th, when the patient began to grow feeble, and was soon confined to his bed. The usual method of treatment had been practised in the case, such as washing out the bladder, etc., and the patient had in this way been made comparatively comfortable. On 25th day of November he began to sink, and died on the night of the 28th of November. Just previous to death he complained of slight pain over the pubic region, but it was not thought to be very severe, for the reason that the patient mentioned the matter only once.

Post-mortem, performed the day following his death, revealed the usual condition of bladder seen in connection with enlarged prostate. The main point of interest was that the abdomen showed evidences of general peritonitis. There was considerable fluid and flocculent material in the cavity of the pelvis, darkish in color, and upon the right anterior wall of the bladder there was found a large abscess.

This abscess communicated with the bladder by two small openings. There was no communication between the abscess and the peritoneal cavity. It is probable that the abscess produced the localized peritonitis which resulted in general peritonitis. Pus had been present in the urine of the patient at different times preceding death, but for a few days before death the urine had been comparatively free from pus. About one month previous to death nearly three ounces of quite pure pus were obtained.

Dr. Post remarked, with regard to the first specimen presented by Dr. Mason, that tumors developed in the course of the large trunks of nerves are, as a rule, less painful than when connected with nervous filaments.

Dr. Post also inquired, in connection with the second case, whether at any time attempts had been made at catheterism, which would give rise to irritation, and was answered in the negative; and also that there was no lesion of the urethra or bladder other than those mentioned.

CASES OF CALCULI FROM BEIRUT.

The presentation of specimens having been concluded, Dr. Post read the following cases reported by Prof. George E. Post, M.D.:

CASE I.—A chain of seven urethral calculi in the bulbous and membranous portions of the urethra.

A young sailor contracted gonorrhea eight years ago. Since that time he has always had difficulty in the passage of urine, and has complained of burning and of the admixture of pus, and occasionally blood, with his urine.

He presented himself at the clinique of St. John's Hospital on account of a hard tumor, just behind the scrotum, in the anterior portion of the bulb of the urethra. This tumor seemed to the touch about the size of a filbert, and communicated a slightly gritty sensation on being rubbed. I passed sounds of various calibres from 12 to 4 to the seat of stricture, which was just in advance of the tumor, but failed to touch any calculous body. I then seized the tumor between the thumb and forefinger of the left hand, and cut down upon it in the median line, and discovered it to be a phosphatic calculus of the size and shape of a filbert. Its posterior facet was indented with a smooth facet, like the adjacent articular surfaces of two carpal bones, and in this facet was a small flattened cubical calculus of the size of a pea. The posterior aspect of this calculus had a similar facet connected with a third calculus, and by slightly enlarging the incision into the bulb, and introducing the left forefinger into the rectum, and pressing forward and upward from the prostate towards the bulb, I was enabled, with the aid of a director, to press and pry out six of the smaller calculi, which, with the larger anterior one, had formed a chain an inch and a half in length, occupying the bulbous and membranous portions of the urethra. The total weight was fifty-four grains. There was some hemorrhage, which was restrained by pressure, and by the application of liquor ferri perchloridi. After extracting the calculi I divided the stricture into the wound.

CASE II.—A young man, aged 20 years, had been cut for stone by the recto-perineal operation at the age of eight years. There remained a recto-vesico-perineal fistula from the time of the operation. At the age of 20 he applied to the clinique of the Hospital of St. John, at Beirut, on account of a tumor as large as a goose-egg in the perineum. On probing through the fistulous openings a large calculus was discovered. I at once cut down upon it in the median line, and removed an irregularly pear-shaped calculus three and a half inches in length, and one inch and three-quarters in diameter at the larger end. It was covered with facets, in which were lodged more than thirty smaller calculi, varying in size from a nickel three-cent piece to a grain of rice. Most of them were nummular in shape, and the nuclei were found to be, in every case, grape-seeds, which had passed from the rectum into the fistula, and lodged by the side of the calculus, and became the nuclei of calculous deposits. The large sac which contained these stones was then dissected away, and only enough of its lining left to form a new urethra. The

anterior portion of the urethra, which from long disuse had become contracted, or rather the development of which from non-use had become arrested, was then divulsed by Perrevis' dilator, and the subsequent treatment as in cases of perineal section with extensive loss of tissue. Unfortunately the patient insisted on leaving the hospital before the final result of the operation was attained.

CASE III.—A man, 45 years of age, presented himself at the clinique of St. John's Hospital for vesical calculus. On making the usual incision for the bilateral operation, and reaching the membranous portion of the urethra, a pouch was felt at its junction with the bulbous portion, which, on being felt between the thumb and forefinger, communicated a grating sensation. It had not been detected by the sound. On laying it open a dozen calculi were evacuated, varying from the size of a lentil-seed to that of a pea. The prostate being incised, a somewhat larger number of calculi was withdrawn from the bladder. The patient had a speedy and perfect recovery.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Jan. 15, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

TRANSFUSION.

THE subject presented to the Academy was that of "Transfusion," by Dr. Fordyce Barker. His remarks were accompanied by the exhibition of Aveling's instrument for Transfusion. The Doctor spoke substantially as follows:

The notion of transfusion of blood from one individual to another was entertained by the ancients. Ovid, in his *Metamorphoses*, refers to Medea, the sorceress, as having power to rejuvenate old age, restoring to youth and vigor, by two processes; namely, by injecting into the veins the juice of certain herbs, and by injecting into the veins the blood of a young person. Practically, however, this experiment, so far as known, was never attempted by the ancients.

In 1657 Sir Christopher Wren, having made some experiments, suggested the possibility of the operation, in a communication which he made to the Royal Society of London in the same year.

In 1665 Dr. Lower experimented by transfusion of blood from one animal to another, and at about the same time Denys, of France, working independently, commenced a series of experiments of like nature. To Denys belongs the honor of being the first to perform the operation upon the human subject, which was done in the year 1666, and was a success. The operation was performed upon a young person who was sick with fever, and had been bled, vomited, and purged twenty-two times. The surface of the body was cold, the patient was pulseless, respiration was extremely rapid, mind delirious, etc., when Denys proposed transfusion, by which means he succeeded in restoring his patient and complete recovery followed. His second case was one of very similar character, and occurred in the person of the son of a Minister Plenipotentiary to Paris, who had been bled in the treatment for a fever until extremely exsanguinated. Transfusion was performed, and a similar success followed the operation. The results of these two operations gave rise to the most extravagant enthusiasm. It was alleged that the insane could be cured in this manner, and that the old could be made young. In the course of one year, however, so many fatal results had taken place, that the

operation was interdicted by law, except as it was permitted by the Faculty of Paris. If that body granted permission, the operation could be performed.

From that time until 1685 the operation fell into disuse in all parts of the world. In 1685 Prof. Harwood, of Cambridge, commenced a series of experiments upon animals. In one of his experiments, which was performed upon an old horse, the animal is said to have raised up and commenced feeding.

In connection with a communication made by him to the Royal Society in England, a man by the name of Cogor consented to have the operation performed by taking the blood of a sheep, and it is reported that the man suffered no harm from the experiment. A second experiment was performed upon the same man, but no history of the result can be obtained. No attempt, however, was made to resort to this operation for the purpose of restoring life in desperate cases until 1819, when the experiment was revived by Dr. Blundell, of London. He commenced a series of experiments to determine what would be the results of transfusion of blood from a vigorous animal to one that was feeble and exhausted. His experiments were characterized by great research and great mechanical ingenuity, and he was the first operator to apply the measure for the saving of life in cases of post-partum hemorrhage. He resorted to the operation in six cases of post-partum hemorrhage, and for a time his patients rallied.

There was a marked improvement in the action of the heart and the respiration, but all of his cases terminated fatally. As far as I have been able to learn, the first case in which the operation was resorted to in connection with post-partum hemorrhage, in which the life of the patient was saved, was a case of Mr. Waller in the year 1859. His patient had suffered in the extreme from hemorrhage, when about $\frac{5}{16}$ of blood taken from the arm of a healthy man were injected into the veins of his dying patient, and was followed by complete recovery.

In all these early cases the transfusion was indirect. The blood was first taken from the system of one person, drawn into a syringe, and then thrown into a vein of the person upon whom the operation was to be performed. At this time the subject had been taken up and examined with great zeal and industry by various German physiologists, and the results of their experiments seemed to prove that the cause of death in these cases was from coagulation of blood. It is to be remembered in this connection that at the time of those investigations the knowledge which we now have relative to thrombosis and embolism did not exist.

While the principle was recognized that blood could coagulate within the vessels, the true explanation was not understood, and different terms were employed to express the idea. In 1860 Prof. Martin operated upon one case, and succeeded in restoring the life of the patient. In 1861 he published a tabulated statement of 57 cases in which transfusion had been performed, and in which recovery took place in 45 cases. In all these cases transfusion was resorted to on account of post-partum hemorrhage. In connection with the fact that danger arose from coagulated blood, it was suggested that perhaps the operation would be rendered more safe if the blood was defibrinated; consequently subsequent experimenters were in the practice of defibrinating the blood by whipping it with a thin rod.

In 1860 Prof. Nusbaum performed the operation in connection with a case of disease of the knee-joint. His patient was so exhausted by the disease that resection of the joint could not be performed. Trans-

fusion was resorted to, and the strength of the patient was re-established to such an extent that the operation was subsequently performed, and was followed by complete recovery.

The same year Prof. Esmarch resorted to transfusion in a case where profuse hemorrhage had followed amputation of the leg. He made use of calf blood, but the operation was unsuccessful.

In the same year Dr. Flint, Jr., performed the operation in the city of New Orleans, but the details of the case the Doctor, being present, will himself relate.

In 1862 — of Stuttgart resorted to the operation in a case of exhaustion dependent upon an alarming hemorrhage in a case of abortion, and the woman was restored to complete recovery.

In 1864 Graily Hewitt proposed an apparatus for performing the operation, which consisted of a syringe so arranged that blood could be received into the open mouth of the instrument by means of a needle something like the ordinary hypodermic needle, and through this needle the blood was to be introduced into the vein.

Dr. B. W. Richardson proposed that gravitation alone should be the medium by which the blood should be transferred to the patient. To secure this the blood was to be drawn directly into a basin, which was to be elevated some inches above the level of the body of the patient. In that manner, he claimed, the blood would be transferred slowly, and the tendency to coagulation prevented.

He also urged that, in case a syringe was used for the transfer of the blood, the blood should first be whipped.

In 1868 J. Braxton Hicks, in Guy's Hospital Reports, mentions six cases in which the operation was performed, and in all the operation was unsuccessful.

He proposed, in order to prevent the tendency to coagulation, to mix with the blood a solution of phosphate of soda. Three grains of the soda were to be added to a pint of water, and then one part of the solution to three of blood was employed. In four of his cases the operation was followed by a temporary rallying of the patients, but death seemed to be produced by certain organic causes. So far as the operation of transfusion was concerned, Hicks regarded these cases as being successful, although all six of his patients died.

In 1871 Belina reported seven cases in which the operation was performed in connection with flooding after abortion. Defibrinated blood was used, and all his cases recovered.

Dr. Higginson, of Liverpool, has reported thirteen cases in which the operation was performed, ten of which were in obstetric practice. The blood used was not defibrinated, and four recoveries followed the operation.

Dr. Ringland, of Dublin, has also reported one successful case.

In this city, to my knowledge, the operation has been performed six times, but in no case has it been successful.

In the first case the operation was performed for the restoration of a woman who had fallen into a condition of extreme exhaustion incident to hemorrhage following the removal of a polypus. Her kidneys were in an advanced stage of Bright's disease.

The following notes of the case have been furnished me by Dr. F. J. Metcalfe:

"Not having any regular apparatus for the operation, the house-physician had to improvise as well as possible. A ligature in the form of a bandage having been placed above and below the vein, at the bend of

the left elbow, the vein was opened, and the end of a fine nozzle, fitting to a three-ounce syringe, was introduced and made fast by a ligature to the vein. The median basilic of one of the doctors present having been opened and seven ounces of blood drawn, this was beaten up in a vessel with a thin whip, for the purpose of keeping it from coagulating, and was then injected into the left median basilic of the patient. In this way thirteen ounces of blood were injected. At the beginning of the operation the pulse was 130, small and feeble, temperature much fallen, skin cold and clammy, respiration 15, and woman comatose. Whilst the blood was being transfused the pulse fell to 100 or 102, and grew fuller and stronger, respiration more forcible, and the body became warmer. As soon as the syringe was withdrawn to be refilled, the pulse went up. After all the blood had been injected, the patient was given a teaspoonful of brandy and $\mathfrak{M}$.v. of tinct. digitalis every ten minutes for an hour. This had its beneficial effects for some six or eight hours, but the patient finally died at the end of forty-eight or sixty hours after the first operation."

The second case was one of post-partum hemorrhage. The patient rallied, but did not recover.

The third case was one of gastritis of a very severe form. Transfusion was followed by temporary benefit.

The fifth case was one in which the operation had been performed subsequent to the operation of ovariectomy. The following notes are from Prof. T. G. Thomas, who had charge of the case:

"Patient vomited for nine days after ovariectomy, and was sustained by enemata alone. At the end of that time her strength failed so completely that, as I saw death approaching from sheer exhaustion, I injected into the median basilic vein $\mathfrak{z}$ viii. of defibrinated human blood with a large vulcanite syringe. No sensible effect was produced, and death occurred a short time after the operation. Fifteen years ago," says the Doctor, "I saw Dr. Van Buren perform the same operation upon a patient who had vomited blood to complete exhaustion. No good result followed the operation, and the patient died soon after. Post-mortem revealed large fatty liver, with open vessels over surface of stomach. Patient a drunkard. Autopsy performed by Dr. C. E. Isaacs."

The conditions which indicate the operation of transfusion are such as are obtained after hemorrhages, and such as are obtained in connection with anemia, cholera, leucocythemia, pyremia, vomiting of pregnancy, etc. The number of cases of recovery, after resorting to the operation, is seventy-seven, which is sufficient to warrant a more general adoption in practice than it now receives.

Within the past two years several successful cases have been reported in England, in which the patient had been brought to very extreme exhaustion from loss of blood. Some of these cases have occurred after abortions, and some of them have occurred at full term; and the blood has been transfused directly from the donor to the receiver by means of an instrument which has been devised by Dr. Aveling, physician to Chelsea Hospital for Diseases of Women. (For a complete description of the instrument, and the advantages claimed for it, the reader is referred to "New Instruments," in the present No.). The success of this operation, like the success of very many other great operations, will be just in proportion to the precautions of all the details and perfect familiarity with every step of the operation, in order that it may be performed with dexterity, ease, and safety to the patient.

Assistance for fulfilling these indications, it is be-

lived, is better afforded by the instrument of Dr. Aveling than by any which has yet been devised.

DR. PEASLEE remarked that he had been struck with the fact that the use of so small a quantity of blood had caused the recovery of the patient in many reported cases—some cases where, perhaps, no more than $\frac{1}{2}$ li. or $\frac{1}{4}$ iv. of blood had been injected, and yet the cases had terminated in recovery. He had been inclined to reject these individual cases as certainly not being very reliable; but there are cases which prove that transfusion, without any chance of contradiction, has saved the life of the patient. It is probable that many cases in which the operation has been tried have not been fever cases, and it is to be hoped that such an instrument as that invented by Dr. Aveling may prove safe and reliable.

DR. BANKER desired to call attention somewhat more definitely to cases of excessive exhaustion resulting from the sickness of pregnancy. The propriety of producing premature labor in certain cases is now pretty well settled; still, patients do fall under observation in which there is so much exhaustion that it would be folly to resort to the procedure in actual fear that death may thereby be produced. It is in this class of cases that the operation of transfusion would be suggested, in the hope, at least, of restoring the strength of the patients sufficiently to enable them to withstand the shock of the operation which is sometimes so imperative.

DR. AUSTIN FLINT, JR., remarked as follows with regard to a case in which he had performed transfusion in New Orleans, in the winter of 1860-61:

The nature of the sickness he was not familiar with; he was called simply for the purpose of performing the operation. The patient was in a moribund condition, and the operation was performed, as the last means for restoration, by means of an ordinary injecting instrument. The blood to be injected was taken in a full stream from a vein in the arm of the husband, received in a vessel which was immersed in water at 100° , immediately taken from the vessel into a fine syringe, and injected as quickly as possible into the veins of the patient. About $\frac{3}{4}$ vii. of blood were thrown into the veins at three different operations, with a few minutes' interval. Immediately following the operation the patient showed an improvement in both pulse and respiration. She somewhat awakened from the comatose condition which she was in at the time of the commencement of the operation, and the opinion was expressed that her life had been prolonged from twelve to sixteen hours. Death occurred twenty-four hours after the operation.

The Professor then spoke of the operation from a physiological point of view. What seems to be the mechanism of the influence by which comparatively small quantities of blood, introduced into the circulation of a person dying either from hemorrhage or from exhausting disease, produces restorative results? It was to be remarked, however, in the first place, that the instrument which had been presented and recommended was simple in its construction and application; and simplicity of the apparatus is the only means by which the operation can be properly performed and introduced into general use.

Again, this operation should be performed much more frequently than it has been, and its use should not be confined to that class of cases where success, at best, would be almost impossible. There are cases in which exhaustion is produced not only by direct loss of blood from hemorrhage, but as the direct influence upon the system produced by disease. There are some cured after the operation. Within half an hour after

diseases attended with great discharge of fluid from the body, where patients have been restored by transfusion. When the successful and unsuccessful cases are collected, it is found that the successful cases are exceedingly numerous; much more so, at least, than would be imagined from the reports concerning the operation as given in this country.

The only satisfactory physiological consideration to be acted upon in the performance of the operation is to take blood from a healthy person and introduce it into the veins of the patient without cooling or contact with foreign substances, and without defibrination. In physiological experiments this operation is a very common one. The artery of one animal is made to communicate with the artery of another animal in such a manner that the artery of the vigorous animal pumps blood into the system of the dying animal, and restoration is established almost with certainty. This is an experiment, however, which probably would not be practicable upon the human subject.

A few ounces of blood transferred from one person to another, after the manner of transfusion, will produce very decided results. Normally, the patient should have from fourteen to eighteen pounds of blood circulating in the system to properly sustain the functions of the body; but the introduction of from $\frac{3}{4}$ iv. to $\frac{3}{4}$ viii. of blood into the circulation of a person apparently dying, has been known to restore such a person to life.

All portions of the blood have been injected without the red blood-globules, but all those cases have been unattended with good results. It is the red blood-globules that seem to perform the necessary work. The red blood-corpuscles are oxygen carriers. That is their function, or, at least, we are not certainly acquainted with other functions if they exist. Respiration consists in an appropriation of oxygen by the tissues, and the introduction of air into the lungs and taken up by the red blood-globules is secondary to real respiration. In order that appropriation of oxygen by the tissues may take place, it must be carried to the tissues by the red blood-globules, and these anatomical bodies are the only agents which can carry it.

When a person is partially asphyxiated, it is noticeable that the lividity of the countenance disappears and the natural color of the face is restored by the admission of air into the lungs. The blood takes up the oxygen of the air entering the lungs, conveys it to the tissues, and when it has reached that point, and yielded the oxygen to the tissues, the lividity rapidly disappears.

There is doubtless diminished power in the blood for carrying oxygen to the tissues in the cases in which transfusion is ordinarily resorted to, and that necessitates a few additional ounces of blood to give an impulse to the circulation, bridging over, as it were, for a time by furnishing it with a fresh supply of oxygen.

The operation is to be regarded as practicable, and should be employed not exclusively in those desperate cases where favorable results are hardly looked for, but should be resorted to before patients have arrived at, and fallen into, this desperate condition.

DR. LUSK called attention to a possible sphere of usefulness for the operation which had not been alluded to, namely, in cases of blood-poisoning.

He briefly referred to a case of puerperal convulsions which occurred in Heidelberg, in which there was every reason to believe that they were due to uramic poisoning. The patient had as many as twenty convulsions, and was completely insensible. About $\frac{3}{4}$ iv. of blood were drawn from the arm, and about $\frac{3}{4}$ vi. of healthy blood were substituted. Only a single convulsion oc-

the operation the patient opened her eyes, consciousness was gradually restored, and recovery was complete. It is possible that in this operation we may yet find a method for successfully meeting this class of cases.

Dr. PEASLEE suggested that a series of experiments should be performed to determine whether blood could be transfused with safety from animals of one species to animals of another species. In this manner, perhaps, it may be found that the blood from some species of animals can be introduced with safety into the human system.

In cases of exhaustion from profuse hemorrhage, in general, if life can be restored for twelve hours, the patient will probably be in such a condition that life may be saved. In cases of exhaustion depending upon the effects of disease, the repetition of the operation would probably become necessary, yet he saw no reason why patients could not be saved in that manner.

Dr. FLINT, Jr., remarked with regard to the suggestion of Dr. Peaslee concerning experiments upon animals of different species, that the subject had already been fully investigated by physiologists, and it had been found that the introduction of blood from inferior animals into the circulation of the human subject is attended with very great risk. Very small quantities of blood from an inferior animal have been introduced into the circulation of the human subject without detriment, but the introduction of any considerable quantity would, without doubt, be an exceedingly dangerous experiment to perform. The experiment of introducing the blood of an animal having oval corpuscles into the circulation of an animal whose blood contained round corpuscles, has already been tried for the purpose of ascertaining, if possible, the length of time occupied by the oval bodies in making the round of the circulation. Experiments of similar nature have also been performed upon sheep and dogs, etc. In all these cases, however, death subsequently followed, which showed that the animal would not tolerate any considerable quantity of blood in the system that had been taken from one of another species.

New Instruments.

AVELING'S APPARATUS FOR IMMEDIATE TRANSFUSION.

The apparatus consists of the following: an India-rubber bulb, oblong in shape, and of sufficient size to contain two fluid drachms; India-rubber tubes six or

patient; the other round-pointed, called the efferent tube (seen at B), which is to be inserted into the vein in the arm of the donor. Also, a pair of fine forceps and a scalpel.

The apparatus is represented in the wood-cut as being in position for the operation.

MODE OF OPERATION.

First, place the apparatus in a basin of tepid water, and, while completely under the water, for the purpose of filling it and insuring its cleanliness, compress and expand the bulb until the air contained within the bulb and rubber tubing is completely expelled. When the air has been completely expelled, and while the apparatus is yet remaining beneath the surface of the water, turn the stopcocks at both extremities of the rubber tubing in such a manner as to entirely preclude the possibility of air gaining access to its cavity. The patient having been brought to the side of the bed and the arm made bare, a fold of skin over a vein at the bend of the arm is to be raised, transfixed, and divided. The vein now brought into view is to be seized with the fine forceps, slightly raised, and a small opening made into it for the reception of the bevel-pointed silver or afferent tube. This tube, which has been lying in the basin of tepid water, should carefully be kept filled with water when it is removed, by placing the thumb or finger over its larger opening.

The tube, now being filled with water, has its bevel-pointed extremity at once inserted into the opening already made in the vein, and is then entrusted to the care of an assistant (A), who carefully compresses the edges of the wound around the tube, and at the same time holds his thumb or finger over its larger opening to prevent the escape of the water.

While the operator is performing this part of the operation, an assistant should prepare the arm of the blood-donor in the same manner as for venesection. An opening is then made into the vein, and the round-pointed or efferent tube at once inserted with its point towards the fingers. The donor should then be seated in a chair at the bedside of the patient. It is better not to secure the tubes in the veins by ligatures. B represents the hand of an assistant holding the efferent tube carefully compressed within the lips of the wound, in the same manner as with the afferent tube at A.

The India-rubber portion of the apparatus, thoroughly cleansed, air perfectly expelled, and completely filled with water, is now to be carefully and closely adjusted to the two tubes in the veins. When adjusted, the stopcocks are turned straight, and transfusion is commenced by first compressing the India-rubber tube on the efferent side (donor's) and then squeezing the bulb which forces two drachms

seven inches in length attached to the extremities of the bulb; and stopcocks attached to the outer extremities of the tubes. Also, two silver tubes: one, bevel-pointed, called the afferent tube (seen at A), which is to be inserted into the vein in the arm of the

of water into the afferent vein. Next, while the bulb is compressed, shift the hand and compress the India-rubber tube upon the afferent (patient's) side. Then allow the bulb to expand slowly, and blood will be drawn into it from the donor's vein. When the

tubing and bulb are filled, bring the hand back, compress the tube, follow this by compression of the bulb, and two drachms of blood will be thrown into the afferent vein. In this manner the process can be repeated any number of times desired, rapidly or slowly, and the exact amount of blood transfused can be known by counting the number of times the bulb has been emptied, and subtract one, which accounts for water first used.

The advantages claimed for this method of transfusion are:

(1.) The chances of coagulation are small, because the blood is removed from the action of the living vessels for only a few seconds, and glides smoothly through the India-rubber without being exposed to the air.

(2.) The apparatus is effective, simple, portable, inexpensive, and not likely to get out of order.

(3.) The operation is safe, easy, uninterrupted, and a close imitation of nature.

Medical Items and News.

HENRY BAYLIS, M.D., who died recently at Mount Hope, Bristol, L. I., was a son of Dr. Gustavus Baylis, who fought in the Revolution, and was army-surgeon during the War of 1812. After graduation at the College of Physicians and Surgeons, he practised successfully in this city fourteen years. He took a leading part in founding the New York Lying-in Asylum, and was attending physician thereof for eight years. Dr. Baylis was an excellent physician, a good citizen, and a generous, noble-hearted man.

FRANCIS MARKEE WRIGHT, of Englewood, N. J., died on Monday, March 16, 1874.

LEGALIZED DISSECTION.—Judge Pratt rendered the following decision on the mandamus obtained by counsel for the Long Island College Hospital compelling the Coroners to show cause why the unclaimed bodies at the Morgue should not be given up for medical purposes:

In the matter of the Long Island College Hospital against the Coroners of the City of Brooklyn, and the keepers of the Morgue of the said City of Brooklyn: On reading and filing the affidavits of Samuel G. Armor, A. J. C. Skene, and A. H. Bates, members of the Faculty of the said Long Island College Hospital, and the order to show cause herein, dated March 11, 1874, and after hearing Daily & Brower, attorneys for the said Long Island College Hospital, and Thomas H. Rodman, District Attorney of Kings County, for the said Coroners and keepers of the Morgue:

Ordered—That the said Coroners of the City of Brooklyn, and the keeper of the Morgue of the said city, be and are hereby ordered to deliver up to the Professors and teachers, on an order of the Dean of the Faculty of the said Long Island College Hospital, the remains or body of any deceased person, for the purpose of medical and surgical study, provided that said remains shall not have been regularly interred, and shall not have been desired for interment by any relative or friend of said deceased person within twenty-four hours after death; provided also, that the remains of no person who may be known to have relatives or friends shall be so delivered or received without the assent of said relatives or friends, and provided that the remains of no one shall be so delivered or received who has been detained for debt, or as a witness, or on suspicion of crime, or who shall have ex-

pressed a desire in his or her last sickness that his or her body may be buried, but such remains shall, in the cases specified in this proviso, be buried in the usual manner; and provided, also, that in case the remains of any person so delivered or received shall not be subsequently claimed by any surviving relative or friend for interment. And the said College shall decently bury, in some public cemetery, the remains of all bodies after they shall have answered the purposes of study, as aforesaid.

ANNUAL REPORT OF THE SUPERVISING SURGEON OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES, for the fiscal year 1873. Washington: Government Printing Bureau, 1873.—This is the second of the series of reports made by Dr. John M. Woodward since his accession to the duties of Supervising Surgeon of this bureau, and, in even greater degree than the one preceding it, does honor to his judgment. Following the customary statistical report and a comprehensive statement of the laws and regulations governing the service, is an appendix embracing one hundred of the one hundred and fifty pages of the work, and composed of essays of considerable interest to the profession, the most important being an article on "Hospitals and Hospital Construction," by Dr. Woodward; "The Natural History of Yellow fever in the United States from 1665 to the Present Time," by J. M. Toner, M.D.; "The Reports of the Marine Officers on the Yellow Fever Epidemic of 1873;" "The Sailor and the Service at the Port of New York, by Heber P. Smith, M.D.; and River Boatmen of the Lower Mississippi, by Orasmus Smith, M.D., of New Orleans. A singular case of double diaphragmatic hernia is reported by Thos. T. Minor, M.D., and illustrated by a photograph, and Dr. C. N. Ellinwood contributes an article on urethral stricture.

The necessity for a marine hospital at this port it is proposed to meet by the construction of the requisite buildings on an artificial island to be located on Oyster Reef, in New York Bay, south of Bedloe's Island. The articles relating to the condition of sailors in this port, and the Mississippi boatmen, are of very general interest, and cannot fail to make a strong appeal for the passage of laws which will ameliorate the condition of these classes.

VETERINARY SURGERY IN FRANCE.—The *Recueil de Médecine Vétérinaire* publishes some interesting details on the present state of veterinary studies in France. There exist three schools of veterinary surgery, one near Paris, at Alfort, a second at Lyons, and a third at Toulouse. They include a total number of 665 students, forty of whom belong to the army, and are supported by the government. Among the total number are 238 students, the expenses of whom are half paid either by the government or provincial departments. The cost of the three schools to the government is about 663,000 francs, 298,000 francs of which are covered by the receipts. The present state of the schools is said to be most flourishing.—*The Lancet*.

JEAN CRUVEILHIER.—A Paris telegram announces that Jean Cruveilhier, the eminent physician, is dead. This venerable man was born at Limoges in 1791, studied under Boyer and Dupuytren, and became attached to the faculty of Paris in 1825. He reorganized, in 1826, the old Anatomical Society which had been founded in 1769 by Dupuytren, and was in succession physician to three of the principal hospitals in Paris. In 1841 he completed his great work on pathological anatomy, forming two large volumes. He also

wrote a book on descriptive anatomy, and one on the anatomy of the nervous system. M. Cruveilhier was appointed a commander of the Legion of Honor in 1869.

UNIVERSITY OF PENNSYLVANIA.—One hundred and twenty-one students have just graduated from the medical department of the University of Pennsylvania. Eighty-one also graduated from the College of Pharmacy.

INCREMATION AND URN-BURIAL.—Prof. Brunetti (*Rev. Scientifique*, Nov. 22) gives the details of the apparatus that would be required for the process of incremation. After having made several experiments on the human subject, in which the bodies were burnt in the retorts of gas-manufactories in closed receptacles, and with free access of air, he first satisfied himself that the complete and perfect performance of the process would be impossible under all ordinary conditions. In the first place, there is required an oblong furnace of fireproof bricks, having ten holes below, by means of which the intensity of the fire can be regulated. The upper part of this should be hollowed to receive the coffin, and over this a domed cover is to be placed, by which the flames, as in a reverberatory furnace, may be directed upon the body. Within the coffin is a metal support, or table, on which the body rests, fixed by thick iron wire. The operation embraces three periods—the heating of the body, its spontaneous combustion, and, finally, the incineration of the soft parts, and the calcination of the bones.

During the first period, and about half an hour after the pile of wood within the furnace has been lighted, the combustion of the body commences. It gives off a large quantity of gas, and the management of the reverberatory part of the furnace is of great importance.

During the second period, the spontaneous combustion of the body takes place, which, M. Brunetti remarks, produces a profound impression on the mind—"impression toujours l'esprit et vous rends pensif."

If the wood has been well arranged, two hours suffice to produce complete carbonization. During the third period, the air-holes being opened, the carbonized mass is collected and placed upon a fresh plate, and the heat is now urged to the utmost, a fresh supply of wood being inserted. By means of this arrangement, at the expense of about 150 pounds of wood, complete incremation—that is to say, incineration of the soft parts and calcination of the bones—may be effected in two hours. When the furnace has cooled, the cinders and bones are collected and deposited in a funeral urn. Prof. Brunetti found the body of a woman, aged thirty-five, weighing about one hundred and ten pounds, reduced to about four and a half pounds. A man of forty-five, weighing about ninety pounds, was reduced to less than two and a half pounds.—*The Lancet*.

GENERAL ELECTRIZATION IN GERMANY.—Beard and Rockwell's work on Medical and Surgical Electricity has recently been translated into German by Dr. R. Väter of the University of Prague.

The translator, in his preface, after giving his reasons for translating the book—that it contained the essence of all previous works on the subject and was especially conspicuous for the truthful delineations of their cases and for clear explanations of the physical and physiological relations of the subject—thus speaks of their method of general electrization:

"A part of the work is given to general electrization, which is useful for the special as well as the general practitioner. Although general electrization had been used before by some electro-therapeutists, yet to Beard

and Rockwell belongs the credit of having given it a scientific basis and reduced it to a system. Of the advantages which may be derived from this method I have thoroughly convinced myself. I can therefore conscientiously recommend the employment of general electrization in very many cases."

NEW YORK HOSPITAL.—The Governors of the New York Hospital have purchased the "Thorne" mansion in West Sixteenth st. According to *The Evening Post*, it is on the south side of Sixteenth st., between Fifth and Sixth ays., extending through to Fifteenth st., and comprising eight full lots, of which five are on Sixteenth and three are on Fifteenth st. The house is about 66 by 80 feet, and three stories in height. In the rear of this the Special Committee recommend the erection of a reception hospital for acute surgical and medical cases, with a capacity of from 50 to 90 beds. They estimate the cost of the hospital building at \$170,000, of its furniture at \$20,000, and of the engine house, laundry, and vaults at \$30,000. The probable yearly expenses of the reception hospital were estimated at about \$40,000. The recommendations of the committee were unanimously adopted by the Board of Governors, and the Thorne property was secured for \$20,000. The first floor of the house will be used for offices; the second for the library and pathological cabinet; the third floor for the hospital staff, and probably some private wards. Possession will probably be obtained about April 1st. Additional ground in the vicinity will probably be obtained.—*Tribune*, March 18.

THE ALUMNI ASSOCIATION OF THE UNIVERSITY OF PENNSYLVANIA.—The election for Officers for 1874 resulted as follows: *President*, Geo. B. Wood; *Vice-Presidents*, Joseph Carson, Geo. W. Norris, Isaac Hayes, Meredith Clymer; *Treasurer*, R. E. Rogers.

NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—At a Quarterly Meeting of the Board of Managers, held March 18, 1874, Dr. William Cockcroft and Dr. Robert G. Remsen were elected Managers, to fill vacancies in the Board occasioned by the deaths of Drs. Underhill and Roberts.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 5, 1874, to March 18, 1874.

RANDOLPH, Jno. F., Surgeon.—Relieved from duty with Sioux Expedition. S. O. 35, Department of the Platte, March 11, 1874.

BILL, J. H., Surgeon.—Granted leave of absence for 30 days. S. O. 55, Military Division of the Atlantic, March 12, 1874.

BREWER, Jno. W., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Warren, Boston Harbor. S. O. 49, Military Division of the Atlantic, March 5, 1874.

GARDNER, W. H., Assistant Surgeon.—Assigned to duty at Fort Union, N. M. S. O. 34, Department of the Missouri, March 5, 1874.

O'REILLY, R. M., Assistant Surgeon.—Assigned to duty with Sioux Expedition. S. O. 35, c. s., Department of the Platte.

CLEARY, P. J. A., Assistant Surgeon.—Assigned to duty at Camp Supply, Indian Ty. S. O. 34, c. s., Department of the Missouri.

MUNN, C. E., Assistant Surgeon.—Assigned to temporary duty at Fort Independence, Boston Harbor. S. O. 49, c. s., Military Division of the Atlantic.

Original Communications.

ON HÆMOPTYSIS.

By JAMES R. LEAMING, M.D.,

ONE OF THE VISITING PHYSICIANS TO ST. LUKE'S HOSPITAL, N. Y.

(A paper read before the Medical Library and Journal Association, N. Y.)

HÆMOPTYSIS may be divided into two kinds, according to the source of the hemorrhage. It may be simply an exudation through the bronchial arteries and mucous membrane—bronchorrhagia—or it may come from some open branch or branches of the pulmonary artery—pneumorrhagia.

These sources, though both in the respiratory system, are yet widely different in their origin, and the hemorrhages differ equally in their character, significance and danger. One comes from the systemic circulation, the other from the pulmonary. One signifies obstruction in the capillary circulation within the lungs; the other that there is destruction of lung substance. One is not necessarily attended with danger, the other threatens instant death. Different and yet similar as are these two varieties of hemorrhage, they are both described to the popular mind rightly enough by the common term "bleeding at the lungs," a phrase which conveys to the people only an idea of horror. The few cases of sudden death from hemorrhage of the lungs are published far and wide, and are ever remembered. When one spits blood, it is but natural that all interested should fear that his may prove one of the fatal cases. Public fear, as well as other forms of public opinion in regard to medical subjects, have their origin in the profession. Through the profession we hope to so instruct the common mind as to prevent unreasoning fear, and in this way it seems possible we may save many valuable lives.

Only a small number of cases of blood-spitting are fatal of themselves, and yet many of them, otherwise without danger, are the beginnings of fatal illness, because of the fright which they induce and of the wrong treatment of which they are the occasion. The anatomical explanation of these facts is the key to our comprehension of the whole subject. The bronchial mucous membrane, as well as the fibrous sheaths of the bronchi, are supplied with blood by the bronchial arteries, which blood is returned by the bronchial veins, and, so far, the analogy of this circulation to that of the body is maintained. But, in addition to this, there are in the lungs arteries arising from the bronchial perhaps receiving supplies also from the intercostal and the mammary. These arteries go to the parenchyma of the lungs, and are the proper nutrient vessels of the true respiratory system. ("Waters on the Human Lung"—Reississen, Cammann, etc.)

In this place it is not necessary to show that they alone provide nutrient blood for the whole true respiratory system which may be in part fed from the aerated blood of the capillaries and venous radicles of the pulmonary artery and vein. The exact truth on this subject will probably never be known. The singular fact remains that these nutrient arteries have no venæ comites. Their blood makes a short cut, as it were, through the capillaries of the true respiratory system, and becomes aerated even while doing its work, and is then passed immediately into the radicles of the pulmonary vein, never going through the right heart at all, and may be said never to have left the systemic circulation. This anomalous fact in the vascular anatomy of the respiratory system explains how bronchor-

rhagia may be caused by obstruction of the pulmonary circulation. Blood hindered or arrested in the pulmonary capillaries obstructs the blood in the nutrient arteries. These having no veins accompanying, are dammed up and the blood is thrown back into the bronchial arteries; and these again relieve themselves from the accumulation by straining it through their own vascular walls, and hence this is called bronchorrhagia. This form of hæmoptysis is a safety-valve arrangement, and its great object seems to be to prevent injury to the true respiratory portion of the lungs. It not only prevents immediate injury, it does more; it stimulates the organic life of the true respiratory system, and the absorbents take up and carry off the obstruction, whether it be plastic exudation upon the pulmonary pleura, or tubercle in the air-sacs. Bronchorrhagia may arise from two kinds of pulmonary obstruction—from that which is temporary and extrinsic to the pulmonary circulation and also from that which is more permanent and which has its seat in the respiratory system. The first cause, or extra pulmonary, may be from cardiac disease, hysterical passion, great emotion, or extraordinary exertion. The second is from obstruction to the circulation through the pulmonary capillaries, as by plastic exudation upon the pulmonary pleura, tubercles in the air-sacs, vesicular emphysema, cirrhosis of the lung, cancer or benign tumor.

Plastic exudation within the pleura is a frequent and too generally an unrecognized cause. The physical signs of plastic exudation have either been called subcrepitant—sometimes mucous râles, or such as were supposed to indicate capillary bronchitis, or œdema of the lungs. I shall not here attempt any discussion of these points, as that has been partially done in a previous paper (Dr. Brown-Séquard's *Archives of Scientific and Practical Medicine*, March, 1873), but shall merely state that in bronchial hemorrhage, it is practically safer to consider these râles as always indicating plastic exudation within the pleura, notwithstanding any predetermined views that may be held upon this subject. This is not unimportant, nor is it intended to bar discussion, as will be obvious, it is hoped, when we come to speak of treatment. The rationale of this cause may be readily understood if we consider that plastic exudation upon the pulmonary pleura, in addition to the pressure caused by its presence, soon applies that cause effectually by its contraction, and so obstructs the circulation of the pulmonary capillaries immediately subtending the pulmonary pleura.

Tubercle and its inflammatory results are important causes of bronchorrhagia, the more especially as the hemorrhage may draw early attention to the disease, which might otherwise have remained latent until softening and disintegration of tissue had commenced. There is no controversy as to the importance of early knowledge of tuberculosis, nor as to its correct management from the beginning. Gray tubercle—Bayle's tubercle—true tubercle—may be so deposited as to obstruct the pulmonary circulation without furnishing physical signs, except such as are obscure to the general observer and liable to misinterpretation. The expert auscultator can alone read them with certainty. In both tubercle and plastic exudation within the pleura, the capillary circulation of the true respiratory system is impeded. Hemorrhage relieves not only the immediate circulation, but it also stimulates the absorbents to remove the obstruction, whether it be tubercle or plastic lymph. From a pretty long observation of clinical facts, I feel warranted in stating my conviction that I have witnessed this conservative process in not a few cases. The thorough-

ness of the cure may depend upon the promptness and amount of the hemorrhage. This is especially so in first attacks.

When either of the important causes named are complicated with inflammatory products in the pleura or in the lung, the results of older disease, the removal of these products may not be so complete; yet even then a large hemorrhage may do very much to clear them away.

Vesicular emphysema gives rise to another variety of obstruction to the capillary circulation in the lungs. The true respiratory system consisting of bronchioli, infundibuli and air-sacs becoming dilated, bronchorrhagia sometimes follows. The obstruction to the capillary circulation in this dilated state of the true respiratory system results from the elongation and narrowing of the capillaries, so that the blood flows slowly or not at all. In old cases of emphysema some of the air-sacs become destroyed, which still farther interferes with the circulation, both in the pulmonary and nutrient arteries, but with less liability to hæmoptysis, as the system, in old cases, becomes accustomed to the crippled condition, and accommodates itself to it.

Cirrhosis of the lung is another variety of structural change, frequently accompanied by hæmoptysis. It commences generally in childhood or early life, and this history assists in making a correct diagnosis. The similarity of its physical signs to those of phthisis in the third stage makes it necessary that we should treat of it somewhat particularly. In both, there are dullness under percussion, cracked-pot sound, and cavernous respiration, which, if in the upper part of the lung, are sometimes accompanied by mucous gurgling. There will be also in both cases absence of true respiratory murmur, altered and exaggerated broncho-respiratory murmur, and there may be bronchial or tubal breathing. There may be also these rational signs in common: hæmoptysis, cough, expectoration, and dyspnoea. They differ in history and in many of the rational signs. Icteric, loss of strength, night sweats, emaciation, and disease or disorder in other organs, liver, stomach, etc., all belong to phthisis, but not to cirrhosis. In phthisis the amount of circulating blood gradually diminishes, not so in cirrhosis; there is no cachexia in cirrhosis, but it is generally marked in phthisis. Yet the diagnosis of cirrhosis, during an attack of hæmoptysis, must be difficult. A few hints may assist in differentiation. The cavities in cirrhosis are always of moderate size and regular shape, and consequently the cavernous respiration is smoother in character and softer in quality than that formed in the irregular excavations of phthisis. The sound runs along the open bronchus each way in cirrhosis more readily, and is conveyed farther from the cavity than in phthisis. The condition of the digestive organs, fulness and vigor of the capillary circulation, but above all, the history of the long continuance of the case, enables us to make a correct diagnosis. The pathogenesis of cirrhosis is considered to be as follows: inflammation of the bronchial mucous membrane extends to the enveloping fibrous sheath, and interstitial plastic exudation takes place, which, contracting, results in stricture of the bronchus, and dilatation follows behind the stricture. In new attacks of bronchitis, plastic matter is thrown outside of the sheath, enveloping and destroying some of the air-sacs and bronchioles. As the child grows older, the physical signs give evidence of cavities and consolidated lung. This condition of the bronchi becomes more or less complicated with plastic exudation within the pleura, which, suddenly interfering with the capillary circulation of the peripheral air-sacs, may be followed by bronchorrhagia.

Cancer and benign tumors within the chest may also cause hæmoptysis by mechanical pressure, obstructing the pulmonary circulation. But the cases are rare, and it is not necessary to dwell upon them, for, if there be obscurity at first in the physical signs, the rapid progress of malignant disease soon renders the diagnosis clear.

Pneumorrhagia.—The second grand division of this subject is important on account of its great fatality. Fortunately its class is small, yet the terror which it excites is not unlike that produced by the cry of fire in a large assembly, jeopardizing many more lives by the fright and insane action which it induces, than by any intrinsic danger in the thing itself. Pneumorrhagia implies an open branch of the pulmonary artery. For practical purposes we shall consider it merely as the effect of erosion from disease, presupposing a cavity to have been formed. Yet, even in the third stage of phthisis, pneumorrhagias are rare among the number of hemorrhages. Pneumorrhagia is possible after the rapid formation of a cavity, and becomes probable if the cavity be near the root or centre of the lung, where the vessels are large and abundant. The rapid disintegration of tissue renders the branch of the pulmonary artery which passes across or through the decaying mass liable to morbid change, which may take the form either of disruption, resulting in sudden death, or, by shrinking up, become impervious and so remain for years. It is then a matter of great moment to watch the formation of cavities, in what may be called a dangerous position, and to so guard the patient during the unavoidable process as to render this accident of minimum probability. Severe coughing should in such circumstances be allayed by opiates, which before perhaps had been avoided. Exertion and emotion should not be permitted to unduly distend the pulmonary vessels. Small blisters may be constantly changed from place to place over and around the forming or formed excavation, in order to glue the pulmonary and costal pleura together, preventing motion in that portion of the diseased lung long enough for a clot to be firmly formed in the artery. Nature sets us the example, for no cavity appears near the surface of the lung, but that its immediate vicinity is bound down by adhesions. Reisseisen, Marshall, Hall and others, taught that the anastomosis of the pulmonary arteries was general and free. Dr. Canmann (*N. Y. Med. Journal*, 1848), in his experiments, by a series of injections into the blood-vessels of the lung of the sheep, proved clearly that this was a mistake; that instead of there being free anastomosis, there is properly none at all. Each lobulette is a complete type of the lung and has no anastomotic connection with any other part, so that, ordinarily, cavities in phthisis, gangrene or abscess, are rarely accompanied by pneumorrhagia, and only so by the accident of their opening a branch of the pulmonary artery. If the cavity just formed is centric, with no pleuritic adhesions, the rational signs may have been so slight as not to have drawn attention. The patient may be in attendance upon ordinary duties when the first mouthful of blood is raised. A lady-teacher in one of the public schools is standing before her class, giving instruction, when she raises a mouthful of blood, and immediately retires to a side class-room; the blood pours from her mouth and nose and she falls to the floor, and is dead before a messenger can be despatched for help. A gentleman in his bed-chamber touches the bell, and comes to the head of the stairs with a vessel in his hand, and calls to the family that he is spitting blood, and desires a physician. They hasten to his assistance, but he has fallen upon the floor and is dead when they

reach him. Sudden deaths from pulmonary hemorrhage are rare, but they sometimes occur. Other cases of pneumorrhagia are not so immediately fatal; there may be several attacks before the patient succumbs. The cavity may be small, and the open branch small, or the motion in the diseased lung may be resisted by pleural adhesions. In the latter case it is possible the hemorrhage may be arrested permanently. A clot forming in and filling a cavity in a portion of lung restrained from motion, may remain there long enough for the eroded artery to shrink and become impervious. But even if the cavity be small, and the arterial branch small, the frequent recurrence of hemorrhages may finally exhaust the patient. This form of hemorrhagia may be mistaken for bronchorrhagia occurring after extensive plastic exudation within the pleura. But with the absence of cavernous respiration or signs of consolidation of the lung, and with the presence of plastic or subcrepitant râles, the diagnosis need not be uncertain.

Diagnosis.—It needs no argument nor farther accumulation of evidence to show the great value of a clear and correct diagnosis in hemoptysis. It is of the first importance to diagnose between bronchorrhagia and pneumorrhagia. In a large proportion of cases the medical attendant may state in the most emphatic manner that there is no danger, and refuse useless or harmful medication. His presence and the confidence which he inspires relieves apprehension and fright, and by wise advice he may prevent serious consequences. The chances are—perhaps a thousand to one—that a case of hemoptysis is bronchorrhagia. It is best to assume this until a certain diagnosis proves the contrary—which turns on the presence of cavities and consolidation of pulmonary tissue. If there be no cavernous respiration and no evidence of consolidation and in addition, if respiratory murmurs can be heard throughout the lungs, it is clear that there can be no cavities. This determines definitely for the larger number of cases, and those not thus determined may be classed as doubtful in virtue of the same negative evidence. By farther examination we may satisfy ourselves, almost with certainty, that a large majority of these also are cases of bronchorrhagia. If the walls of the cavities are hard and unyielding it amounts almost to a demonstration that the hemorrhage is not pneumorrhagia, for the hardened walls are a sign that the cavities are old, and the branches of the pulmonary artery that traverse them are probably impervious. If cirrhosis of the lung be diagnosed, it is certain that the hemorrhage cannot be pneumorrhagia. When a cavity is forming, or has just formed, without previous disease in that portion of the lung, if the position be central, the progress of the disease rapid and the lung free in its motion, not held by adhesions, the danger from pneumorrhagia is imminent and should be guarded against.

Treatment.—Pneumorrhagia may be so speedily fatal that there will be no time for ordinary remedial measures. It has been suggested that it might be possible to arrest hemorrhage from the lungs likely to be fatal by standing the patient upright until syncope should take place, and then placing him in a recumbent position, so that a clot might form in the cavity. I am not aware that this plan, which certainly has plausibility to recommend it, has ever been intentionally tried in practice. But we know that some of the patients were standing upright when the bleeding began, and fell from exhaustion or syncope, and so had the advantage of this hypothetical method without avail. The appalling cases of pneumorrhagia arise from central cavities of large size and from the erosion of a large

vessel. Should a clot even be formed and the patient recover from syncope, the unhindered motion of the free lung would soon dislodge the clot, and the hemorrhage would again commence. Unfortunately the history of these cases shows that they are too speedily fatal for a clot to form. In a small cavity or in a smaller open vessel there is more likelihood of the formation of a clot, and the temporary arrest of the hemorrhage. But even here, when the cavity forms in the centric or dangerous locality, the clot is soon dislodged and the bleeding recommences, and this alternation continues till the patient sinks exhausted. In this variety of pneumorrhagia, however, there is time for something to be done; the danger is from recurrence of bleeding by displacement of the clot. If this can be prevented long enough the vessel may become impervious and immediate death be avoided. There can be no hope to fill the indication but by mechanical interference; medicines have no power over open vessels in the centre of the lung. Our experience suggests that nature has here pointed the direction that our endeavor must take to afford any hope of success. Motionless lung alone can permit the closing of the vessel. Nature secures this condition by adhesions—we can in some degree imitate her by transfixing the lung in the diseased part, thus holding it still till the danger is past. Needles of platina or gold, passed from different points through the lung, may successfully prevent motion, and they might remain, doing no serious injury, until inflammatory action should be set up, and thus effectually prevent a recurrence of hemorrhage. Or the needle of the aspirator could be passed into the cavity and an injection of a drop or two of liquor ferri per sulphatis or other powerful styptic could be thrown in, which would form a firm clot in the open vessel as well as in the cavity, and the hemorrhage be permanently arrested. This presupposes an accurate diagnosis of the position of the cavity. As before said, fatal pneumorrhagia is not likely to occur near the surface of the lung, where the contiguous pleura is bound down by abundant adhesions, and it is a wise precaution to frequently apply small blisters over and around forming or recently formed cavities. This measure not only guards against pneumorrhagia, but it prevents a cavity discharging its contents into the pleura, causing hydro-pneumo-thorax. Effusion of serum into the pleural cavity arrests pneumorrhagia by mechanical compression, in the same way as we sometimes see it crush out pneumonia. This condition might be artificially produced by pumping water into the pleura. Ligaturing the limbs with a tourniquet or strap is easily performed, and it is a practical and frequently used method of arresting hemorrhages, for it prevents the return of venous blood to the right side of the heart and temporarily relieves the pressure on the pulmonary circulation. The hemorrhagic act is preceded and accompanied by an eager hastening pulse-beat which the medical observer soon recognizes, and advantage may be taken of this monition to gain time for the application of mechanical means. If some of these means suggested seem to be harsh, farther consideration will show that they are not so in reality, and it must be remembered that the occasion is desperate and none other are of any use or promise any hope. Medicines given by the mouth, or otherwise, can have no control over a bleeding artery in the centre of the lung.

In bronchorrhagia there is no danger of sudden death, and consequently there is time to select the best methods of treatment. When the cause is extrinsic to the lungs the remedy should be to the cause and not to the symptoms. In hysteria the treatment should be to the disease, and the same in cardiac affections. The

hemorrhage *per se* gives relief, and when left to itself it may be safely said is never other than beneficial. After an hysterical hemorrhage from the lungs, which may have produced alarming fright in the bystanders, the patient may fall into a gentle and placid sleep, from which she awakes relieved.

Bronchorrhagia arising from obstruction to the pulmonary circulation from a diseased heart must be treated by paying attention to the heart alone, endeavoring to give it force and power to equalize the circulation. Stimulating enemata, brandy by the mouth, mustard foot-baths, the sedative action of calomel, digitalis and nux vomica, may relieve the heart from its oppressed condition and the hemorrhage will cease naturally. Bronchorrhagia resulting from obstructed pulmonary circulation, caused by plastic exudation upon the pulmonary pleura, is of more frequent occurrence than any other, and its mismanagement may be followed by the most serious consequences. The lung oppressed by the presence of plastic exudation is more and more crippled by contraction. A large hemorrhage at the beginning is frequently followed by the immediate removal of the cause. Attempts to arrest this hemorrhage are generally futile, but the evil results of the methods used and the delay in applying proper remedial measures may end in what is popularly known as "hasty consumption." The old custom, lately reinstated by the translation of a popular German text-book, is to place the patient in bed in a semi-recumbent position, to direct that he be kept quiet, to speak only in whispers, not to cough, to darken the room, and prevent all motion that may be avoided. In addition to these medicines are given to stop the hemorrhage, as, acetate of lead, opium, kino, tannic acid, gallic acid, matricaria, ergot, spirits of turpentine, and table-salt. In spite of all this treatment and mismanagement the bleeding continues more or less at intervals, causing prostrating fear to the patient and agony to the loving attendants. This may go on for days or weeks, until nature, giving up the contest, the bleeding may cease, only to be followed by disintegration of tissue, rapid tuberculosis, and death. An entirely opposite treatment might have saved life. But instead, the effort of nature is thwarted and rendered of no effect. The threatening conditions, which she would have changed if she had not been prevented, are carefully preserved, and in addition to all this the exuded blood is kept in the bronchi decaying and offensive, causing local inflammation and general depression. Medicines which do harm to the patient, and do not arrest the bleeding, are resorted to, while all that should be done is left undone. It is no wonder, viewed in this light, that "hemorrhage causes phthisis;" would it not be better to say, rather, that the physician cultivates phthisis? As illustrating the possible consequences of repressing all effort to relieve the clot in cases of hemorrhage, there is an instructive case in Graves, who reports the incident of a gentleman who had several hemorrhages in one day and was visited by Dr. Stokes, who found him collapsed (he had also been bled from the arm) and well-nigh asphyxiated; the right side of his chest was expanding and contracting energetically, the left almost fixed and motionless. Dr. Stokes changed his position and gave him a glass of wine, when he made an effort and violently expectorated a fibrinous coagulum, forming a complete mould of the left bronchus and its ramifications. Loevenhard, quoted by Valleix, cites a case of a woman to whom alum had been administered in hemoptysis with the hope of arresting the hemorrhage, and apparently with effect, but upon the ces-

sation of the bleeding, suffocation became imminent; and from this danger the woman was only relieved by the rejection of a large quantity of coagulated blood.

What then should the physician do when called to a case of this nature? His first determination should be *to do no harm*. He should by his cheerful, confident demeanor, inspire the patient and friends with his own courage. Then after auscultation and the diagnosis of bronchorrhagia, he should insist upon the patient's speaking aloud, that he should breathe freely, sit up, walk about, cough and expectorate all the blood he can. There is no danger of increasing the hemorrhage by coughing, loud speaking, and full respiration; these acts merely help to loosen and dislodge the blood already exuded into the bronchi and which is there obstructing respiration. It should be the object of the treatment to expel all the exuded blood, before any part of it becomes putrid. Clearing out the bronchi and full respiration do not increase the exudation; on the contrary these healthful acts go far to equalize the circulation and help to arrest farther hemorrhage. Salt and spirits of turpentine are innocuous, but do not let the patient believe that they are given for the purpose of arresting hemorrhage; it is best to stand firmly upon the ground that the hemorrhage is beneficial and should not be arrested. On this account we should refuse any medication, for, if the bleeding does not soon cease, the patient begins to lose confidence in the doctor's ability to arrest it, which may be calamitous. The confidence inspired by the presence of one believed to have power to help us, gives tranquility of mind and that steady, nervous action which, operating directly on the heart, equalizes the circulation; the cold extremities become warm, the oppressed breathing becomes free, and these facts prove that the pulmonary congestion or stasis is relieved. Many remedies have gained reputation for power they did not possess, by the *real power* of a trusted physician's presence, acting through the emotions upon the organic life of the body. As soon as a diagnosis can be made between plastic exudation and early tuberculosis, a line of treatment should be adopted not "to cure the bleeding" but to remove the cause. In both plastic exudation and early tuberculosis all the special treatment should be the same. The lungs should be frequently and systematically expanded, as much fresh air should be inspired as the system will accept. The diet should be nutritious, not overstimulating, but such as is known to be most beneficial in tubercular phthisis. If plastic exudation should be diagnosed by finding persistent, subcrepitant or mucous râles, soft-tearing and near the ear, without dulness of the percussion note, its early removal would be an object of the highest importance. Nothing helps us in this object more speedily, perhaps, than the bleeding itself, and for this reason we should not arrest it, even were it within our power to do so. The beneficent and harmless action of calomel when used for its sedative effect, in cases of commencing or threatened inflammation, is not so well known as it deserves to be. In "Graves' Clinical Medicine" (pages 803-806 inclusive, ed. 1843, Dublin) its qualities and capabilities are well set forth. In Dr. Lent's paper (*N. Y. Jour. of Med.*, May, 1869) its successful and safe application in dysentery and some other inflammations is ably maintained. In recent plastic exudation, followed by hemorrhage, its beneficent and prompt effects are more remarkable than they are in any other inflammation. It wipes out, as it were, all evidence of disease, the hemorrhage ceases, the subcrepitant and mucous râles disappear in an incredibly short time, leaving the patient well. It has been un-

fashionable of late years to speak of calomel and bleeding as proper remedies in any case. No doubt they have been abused, and so too have many other good instruments which have not been discarded.

Above all other things it is important that specifics or styptics, of whatever name or character, especially those that may depress the vital power or derange the digestive organs, should be *withheld* in bronchorrhagia. Our one object should be to remove the cause.

THE ELECTROLYTIC TREATMENT OF CANCER.

By A. D. ROCKWELL, M.D.,

ELECTRO-THERAPEUTIST TO THE N. Y. STATE WOMAN'S HOSPITAL.

(Read before the Medical Library and Journal Association of N. Y.)

ANY considerations in regard to the treatment of cancer must of necessity be of little interest or value, unless they are based on some reasonable theory of its origin. The theory of the blood-origin of cancer has in the past been universally accepted, and to-day even it is probable that the majority, both in and out of the profession, believe some *materies morbi* in the blood to be the original cause of the local cancerous manifestations.

Others, while hesitating to accept such a statement unreservedly, look upon the disease as necessarily constitutional. It is not at all strange that such should be the generally accepted view, since Paget, and nearly all the older pathologists, teach that some morbid material in the blood must coexist with some special condition of tissue "appropriate to be the seat of growth incorporating that material." This ancient theory has strong arguments for its support, and it certainly seems hard to explain some of the symptoms of this terrible disorder on any other hypothesis.

I think it may be regarded as fortunate that another theory has been advanced—that of the local origin of cancer in its early stages—and that so many keen observers of the present day have argued so plausibly in its favor. Viewing cancer as primarily a blood-disease, we have very properly and logically adopted constitutional treatment. We have deprecated early extirpation by the knife, and, in the vast majority of instances, operations have been performed only after the growth has been fully developed, and too frequently after the so-called cancerous cachexia has become manifest. On the other hand, if we regard this disease as primarily of local origin, it will be proper to reverse the old and accepted methods of procedure. Early operations will be the rule rather than the exception, and instead of using stimulants and constitutional remedies with a view to counteract the supposed poisonous state of the system, we shall possibly more and more come to recommend a light form of diet, with no stimulants.

This remark applies of course only to the disease in its early stage, and before there is any approach to constitutional disturbance.

Cases are not wanting in which hemorrhoids and certain forms of benign external tumors have become absorbed under a persistently rigid system of diet. It is well known that when the body is feeding on itself it does not spare adventitious tissue, and when, according to Dr. Morgan, a uterine cancer has been known to disappear under a vegetable diet, just sufficient to sustain life, the question as to the possibility of "starving the disease out" is to say the least suggestive.

Hard as it may be at first thought to reconcile some of the symptoms of cancer with other than a constitutional or blood-origin, it seems to me at least equally difficult, after an acquaintance with the views of Virchow and Van Der Kolk, of Mr. C. H. Moore of London, and others, to regard the disease at its first inception other than of local origin—either with or without a constitutional tendency. One of the most interesting and clearly suggestive contributions in support of this theory is the brochure of De Morgan,* whose experience has been large, and whose generalizations are worthy of wide dissemination.

In all ages tradition has ever been regarded as the most conclusive of proofs; hence the general assent to this idea of the constitutional origin of cancer as the only true or even plausible theory. The indisputable fact of the almost universal reappearance of cancer after its removal is one of the strongest arguments in favor of a specific dyscrasia. There are not a few instances certainly where cancer, after extirpation, has never reappeared; but those on the side of its constitutional origin claim that this fact is of but little account as against the doctrine of blood-poisoning, since, after removal, the disease has in many instances returned, after as great a lapse of time as has ever intervened between the extirpation of such growths and the subsequent death from other causes of the individuals operated upon. On the not very well grounded assumption that a cancerous tumor is a sort of eliminating organ, and in its relations to the *materies morbi* occupies much the same position as a secretory gland towards the eliminated matter, it is claimed in these cases of non-recurrence after removal, that the original blood-taint had become exhausted at the time of the operation. Paget again teaches that two conditions are necessary for the development of cancer, viz., a "morbid material in the blood, and a special condition of tissue"—hence the occasional failure of a malignant tumor to reappear after its removal results from the absence of any fit nidus for its reproduction. According to this theory the blood may be cancerous through a long life without any local manifestation of cancer; and if it seems difficult to account for this local manifestation on any other ground than a blood-origin, it certainly seems equally difficult to believe that cancerous elements may be for years flowing through the body and yet give no evidence of its presence.

The cancerous cachexia upon which so much stress is laid may in many respects be said to be a myth. Vary rarely, if ever, are the first manifestations of malignant tumors associated with a cancerous cachexia.

A woman may have a fully developed scirrhus of the breast for months, and even years, and exhibit no marked failure of strength or color, and it is a well recognized fact, that cancer selects frequently the strong and ruddy. In most diseases known to be of blood-origin, there occurs, within a very short time, a manifest deviation from sound health. Syphilis, it is said, may be an exception. The syphilitic taint may exist, for a long time, without any evidence that the system is thus affected, until some external injury may be followed by an outward expression of its presence. On the other hand, it is claimed that injuries, whether occurring before the appearance of the growth, or after its removal, exert no special influence in starting up either a primary or a secondary cancerous development, and so far as concerns the cachexia, not only is it frequently absent, as before remarked, for a long time after the appearance of the tumor, but sometimes even the strength

* The Origin of Cancer, considered with reference to the treatment of the disease, by Campbell De Morgan, F.R.S. J. & A. Churchill, Publishers, London, 1872.

remains fair, the digestion good, the complexion ruddy, for a considerable period during the process of ulceration. In whatever light the subject is viewed, it certainly seems reasonable to suppose that the symptoms of exhaustion and wasting away, together with the attendant cachectic appearance, may possibly be due to the continual absorption of this foulest of all discharges.

The evidence in support of this supposition becomes still stronger from the fact that patients who die from ulcerating cancer become exhausted and waste away, without, in the majority of cases, giving evidence of any cancerous cachexia. Why is it that after the extirpation of a cancerous growth the health of the patient, as a rule, so markedly increases in every respect, and when, through the propagating influence of the germ-matter that is usually left behind, the disease returns,—why is it that the health and strength again fail? Those who advocate the theory that cancer is merely the local manifestation of a constitutional disease would account for this fact on what is termed the secondary cancerous cachexia.

Paget says: "The morbid material is the essential constituent of the cancerous diathesis or constitution; and when its existence produces some manifest impairment of the general health, independent of the cancerous growth, it makes the primary cancerous cachexia." The cachexia present after the cancerous development he terms secondary.

In point of fact, the cachexia termed primary has insufficient ground on which its existence can be based, and even Mr. Paget, in another place, admits that it may not be present. It is well known that when a cancerous organ is removed, the disease seldom returns in its fellow, but frequently appears in places that are rarely the seat of primary cancer. In commenting on this fact, De Morgan very justly remarks, "that if recurrent cancer is a result *de novo* of the continuity of action of a morbid process originating in a diseased state of blood in combination with a fitting tissue, should we not expect that the return would be almost always in some organ which is the common seat of the disease. It is still stranger that it should occur in nineteen cases of twenty in tissues or organs which are rarely the seat of primary cancer."

In these brief considerations concerning the origin of cancer, it has not been proposed to offer anything original or in any way to exhaust the subject. I would merely call renewed attention to the recent theory concerning the local origin of cancer, and suggest that, in the future, we pursue in its treatment a course more directly from the stand-point of this theory.

As a contribution in this direction, I offer the following, and though it proves nothing as to the curability of cancer, it will, I am sure, commend itself as worthy of record.

CASE.—Mrs. H., a married lady, aged about forty, came under my observation, through the kindness of Dr. J. L. Cabell, of the University of Va. The patient was suffering from cancer (scirrhus) of the left breast of about the size of an ordinary orange, and in addition one of the axillary glands was enlarged to the proportions of an ordinary hickory-nut.

She had observed while in India, eighteen years before, a small lump in the breast, but during all the years of her residence in that climate it remained stationary and never annoyed her. About eighteen months before I saw her, she left India for England, and soon after arriving in that colder and damper atmosphere the lump began to enlarge. During the process of its growth she has suffered from occasional neuralgic pains, but of no great severity.

On June 12, 19, and 28, 1873, I operated by the or-

dinary method of electrolysis, on each occasion introducing three needles. These efforts merely resulted in a softer condition of the tumor, with possibly some slight diminution in size, and I determined to extirpate the growth, and to destroy the surrounding tissue by the undermining electrolytic process. The patient went to her home, and in October she returned and submitted to the radical operation. Instead, however, of taking away the tumor by the process proposed, I secured the services of Dr. A. B. Crosby, who on the eighth day, after the patient had been thoroughly etherized by Dr. N. B. Emerson, quickly removed both the breast and the enlarged gland of the axilla.

I had at hand an appliance consisting of some twenty points, projecting from a metal plate an inch and a half long, by an inch in width.

This contrivance, which may be termed a small harrow, was placed on a portion of the surface of the wound, and the operation was continued.

The needles penetrated somewhat into the exposed tissues, and the electrolytic process, which was at once begun, gave evidence of its usual activity. Hydrogen was developed in abundance, and the tissues changed in color and consistency, and rapid and complete destruction followed to a considerable depth. By this method the whole of the freely exposed surface was worked over and destroyed, and those portions that were more or less hidden were treated by two or three ordinary electrolytic needles. It was necessary to observe some caution in the regulation of the strength of the current and the position of the poles, for when the current was increased above a certain point, or, through the position of the poles, affected too directly the pneumogastric nerve, the heart's action became most markedly lowered both in frequency and force. On modifying the influence of the current, however, the circulation became as strong as usual—for a moment, indeed, there was an increased vigor in the reaction. The suppuration, which was quite profuse for a time, was followed by a healthy granulating surface, and in ten days the patient was sufficiently recovered to return to Va., where the healing process progressed favorably throughout.

The points of particular interest and the thoughts suggested by the above case may be thus summed up:

First. Treatment by the ordinary method of electrolyzation resulted only in a slight diminution in the size of the tumor, and it became evident that decided reduction was not to be expected in any reasonable length of time. One of two methods of procedure have generally been attempted in the treatment of cancer by electrolysis; either a few needles have been introduced through which a current of moderate tension is passed, but insufficient to excite the ulcerative or suppurative process, or else a greater number have been introduced and a current of sufficient strength used to effectually destroy the parts upon which it acts. By the first-named method the process of absorption is in some cases excited to a marked degree. Non-malignant tumors, goitres especially, are sometimes dealt with most effectually. A goitre of considerable size and of long standing on the person of a young lady, referred to me by Dr. J. Marion Sims, was completely dissipated by the feeble electrolytic effects following a dozen external applications. The case of a patient at Bellevue Hospital, whom I treated for scirrhus, illustrates the remarkable power of electrolysis to excite absorption. It has been referred to before, but I am impelled to speak of it again on this occasion, since the ultimate fate of the patient is now known—dissipating the hopes that attended the case. I operated

in the amphitheatre of the hospital, using four needles and a comparatively feeble current. No ulceration was excited, but the tumor began to decrease in size, and in a week's time was one-half its original bulk. A second operation was followed by a still further decrease in size. The patient then left the hospital and for many months was lost sight of, and we were led to hope that the absorbing process had gone on to complete dissipation, but she subsequently returned and died of the disease in a remote organ. From my own experience, then, and from what I can learn of the experience of others, it would seem reasonably certain that we are not, as a rule, to expect much that is favorable in the treatment of cancer, by attempting through our present knowledge of electrolytic methods to excite the process of absorption.

The second method—that of introducing a large number of needles and using currents of great strength—has been occasionally attempted and encouraging reports have been made.

Sufficiently well-authenticated accounts of cases brought to a successful issue in this way are, however, it seems to me, wanting. It would be far better to introduce the needles around its base, or, better still, by means of one long, narrow, double-edged blade, to transfix the growth, or rather, transfix the sound parts below the growth, and then, partly by the cutting edges, and partly by the chemical action of the current proceeding from the edges, to remove the tumor at one operation.

The method adopted in the above case, however, seems to me to be superior to either, from the fact that although two distinct operations are performed, less time is consumed in the operation, and it is possible more effectually and to a greater depth to destroy the underlying tissue.

Second. It is worthy of note that the application of the current seemed to be stimulating in its effects. When applied so as to affect too directly the heart, it is true that the heart's action became weakened, but the moment the tension of the current was lessened, or the electrodes removed to another part, the pulse became fuller and stronger.

Third. The healing process was rapid and healthy in all its progress, and the health and strength of the patient, which before the operation were by no means robust, were not at all impaired subsequently. The operation, in short, were followed by no greater prostration than if the knife alone had been used.

I do not present this case as of special importance, further than as it is an illustration of a somewhat new method in the treatment of cancer, founded on the reasonable assumption that it may primarily be of local origin.

The disease may in our patient manifest itself again after a comparatively short period, or it is barely possible that its reproductive power may have been destroyed and the disease overcome.

The first appearance of the growth was many years before; it had been enlarging for nearly two years, and one of the axillary glands was involved; hence it cannot be regarded as typical of cases on which it would be desirable to test this method through a series of years.

So long as we are able to do so little towards the radical cure of cancer, it can never be amiss to refer to any means which will even for a time relieve the awful agony that so frequently attends it.

It is not sufficiently understood by the profession what a magic influence an intelligently directed application of the constant current exercises, as a rule,

over the throbbing pains of scirrhus, especially of the female breast. The woman at Bellevue to whom I referred had suffered most severely for many weeks. After the first introduction of the needles every vestige of pain left her, and during the two weeks that she was under observation, before leaving the hospital, she was entirely comfortable. A number of similar cases might be recorded, but I will offer only the following, which is perhaps of more interest than the majority.

In February, 1873, Mrs. —, a patient of Dr. Everett Herrick, came to me, seeking relief from an immense ulcerating cancer of the breast. The tumor had been removed more than a year previously by Dr. W. H. Van Buren, but the wound did not entirely heal, and a few months subsequently, the ulcerative process began, and steadily progressed. For many months the pain from which she suffered had been of unusual severity.

By the advice of her physicians, above named, she was submitted to localized galvanization of the sound portions surrounding the ulcerating part, and by frequent applications the intense pains were for nearly four months held in almost complete abeyance. At times, however, her sufferings were most intense, and words fail to express the instantaneous and absolute relief that invariably followed the treatment. I would occasionally find her in the morning suffering most acutely. An application would dissipate the pains, and for twenty-four hours frequently, and sometimes for forty-eight, she would move about and rest in perfect comfort. In the latter part of May it was observed that the current did not afford the same relief as formerly. The character of her sufferings had, however, changed. In place of the sharp, shooting pains simulating neuralgia, the distress consisted in a constant burning and itching, which annoyed her more or less until her death some few months subsequently. It must be remarked that her later sufferings were not to be compared with those which the current so effectually allayed.

Was the change in the character of her pains the result of the galvanization, or is it probable that, if left to nature, the characteristic neuralgic pains would in the same way have been replaced by the less distressing symptoms of itching and burning?

It is impossible to say, but it seems reasonable to attribute the changed action to the influence of treatment. It is proper to say that, during the course of treatment, I operated in the presence of Drs. Van Buren and Herrick, by both the galvanocautery and electrolysis, with the vain hope of modifying in some degree the profuse and offensive discharge and checking the rapidity of the ulcerative process. This case was alone sufficient to teach the necessity of care in the application of electricity, and to confirm the statement that it is not so much electricity that relieves and cures as the method of using it. An application too prolonged, or with a current of too great tension, would not only fail to relieve, but on the contrary decidedly aggravate the distress. The cathode, applied to the seat of pain, did not relieve as did the anode.

The pain was for some time overcome by simple localized galvanization, but during the last weeks of treatment the applications were effectual only when the electrodes were separated as far as possible.

DR. SHARPEY, the distinguished professor of physiology at University College, is to be placed on the Civil List for a pension of £150 per annum.

RESECTION CONSIDERED AS A REMEDY FOR ABDUCTION OF THE GREAT TOE —HALLUX VALGUS—AND BUNION.

By DR. A. ROSE,

PHYSICIAN ST. FRANCIS HOSPITAL.

FREQUENTLY the great toe of aged persons is found in the position of abduction—abducted outward from the median line of the body. This abduction has also been called hallux valgus, being analogous to "pes valgus" and "genu valgum," all of which are outward distortions, or deformities due to abduction. Hallux valgus is a kind of incomplete luxation, and is in rare cases the result of an abnormal process of growth. It is observed, however, that the deformity does not generally begin until the body has ceased growing. In a number of cases it is the result of an arthritis—usually of a gouty character—or, according to Hueter, of a panarthritis urica, which attacks almost always the first metatarso-phalangeal joint. In most cases, however, abduction of the great toe is caused by the pressure of ill-made and ill-fitting boots or shoes. If the broad expanse of the heads of the metatarsal bones is forced into a narrow boot, a pressure is brought to bear both upon the great and little toes, resulting in the formation of a corn on the metatarso-phalangeal articulation of the little toe, while the great toe, on account of its greater lateral mobility, yields to the pressure upon its distal extremity, and becomes abducted, occupying a position upon the dorsal or under the plantar surface of the next toe.

Hallux valgus always causes a portion of the capitulum metatarsi to be removed from contact with the phalangeal articular surface, thus inciting a process of hyperplasia on that portion of the articular surface which is relieved from pressure. This condition is followed by a thickening of the synovial membrane, with disintegration and shrinking of the cartilage, so that, in course of time, all the parts of this first and most important of the metatarso-phalangeal joints may become affected (panarthritis).

The head of the metatarsal bone now forms a remarkable protuberance, which is still more enlarged by a bony proliferation of the bony tissue, caused or promoted by the continued pressure upon, and irritation of, the affected joint. Froberg described this affection as an exostosis of the great toe, after the proliferation of the bony tissue has taken place. In most cases, however, there exists only expansion of the bone, and rarely exostosis.

The continued pressure of the boot upon the proliferating articular head may produce a bursa over the enlarged bone, which frequently communicates with the joint. The bursa itself may also, in consequence of continued irritation, especially through cold, become the seat of an inflammation, followed by ulceration and the formation of bursal fistule, which are very difficult to heal, and which may, by perforation, cause an inflammatory suppurative of the joint, with all its evil consequences.

Hallux valgus, like varicose ulcers of the leg, is principally met with among the laboring class, and, according to my experience, medical aid is not sought until the disease is so far advanced as to render walking very difficult; for the poor laborer does not apply for the usual orthopaedic treatment as long as he is able to work.

Cases are reported where tenotomy, bandages, surgical apparatus, methodical motions have been employed in the treatment of this small joint. Pitha devised

an apparatus to be applied during the night, consisting of a sandal, with a steel spring attached to the inner margin of the foot, to be connected with the refractory toe by a broad band. All these orthopaedic appliances are inconvenient, often impossible of application, and always tedious and uncertain in the result, so that very few patients submit to them for any length of time. In fact, these cases are generally abandoned by surgeons as hopeless. We are happy to say, also, that orthopaedic appliances have now been proven to be unnecessary, if only the patient is willing to submit to a simple operation in order to remedy the damage done by the shoemaker.

As an illustration of the misery and anguish caused by hallux valgus, the following instance is related by Pitha: "An old surgeon having suffered greatly from abduction of both great toes, finally, in his 75th year, cured it radically by placing first one foot on a block of wood, and chopping the toe off with a chisel and hammer, and subsequently repeating the same operation on the other foot. In spite of his old age both wounds healed promptly."

Resection of the head of the metatarsal bone has been first recommended by Hueter. He performed it, however, only in those cases in which suppurative of the joint existed, and where it was apparent that no cure could be accomplished without resection. So far as I know, the first resection in a case of simple hallux valgus, uncomplicated with abscess or caries of the joint, was made at St. Francis Hospital, in this city, by Dr. Frank H. Hamilton, April 7, 1873.

The patient, Johann Lang, 24 years old, and a baker by trade, was admitted into Hospital on March 31st, 1873, suffering from abduction of both great toes, in consequence of which he was so completely disabled that he was unable to work at his trade. Dr. Hamilton proposed total resection of the first metatarso-phalangeal joint, when I called his attention to an operation made by Hueter, namely, resection of the distal end of the metatarsal bone, but not in a precisely similar case.

As above stated, Dr. Hamilton performed resection of the head of the first metatarsal bone in this case on April 7th, 1873. The patient having recovered from the operation, and finding the foot operated upon perfectly useful, requested that the same operation should be made on the other foot, which was accordingly done by Dr. Hamilton. Before the second operation was made, however, the patient was presented to the N. Y. Pathological Society, on May 28th, 1873, and in THE MEDICAL RECORD of August 1st, 1873, there is a full description of this first case and first operation. August 4th, 1873, the patient was dismissed from the hospital; but during the last month of his stay he had been employed as a helper, and kept busy on his feet the whole day long.

On June 18th, 1873, another patient afflicted with hallux valgus was admitted into our hospital: Joseph Meyer, 30 years old, laborer, abduction of the left great toe, complicated with caries of the metatarso-phalangeal joint. This patient was operated upon by myself. In place of using the bone-cutter for decapitation of the first metatarsal bone, as Dr. Hamilton had done, I applied the straight, narrow saw, and must confess that, by using this instrument—which was, next to the bone-cutter, recommended for this operation by Hueter—it is impossible to avoid contusing and lacerating the soft parts surrounding the bone. This operation proved equally successful, and the patient was dismissed on September 8th, 1873, perfectly able to assume his work again.

In the third case, E. Z., 34 years old, waiter, there existed an arthritis deformans of all the phalangeal

joints of both feet; the shortening of the extensor tendons produced a hyper-extension of the toes; both great toes were abducted, and both little toes adducted. The operation was made by Dr. Barnim Scharlaw, who first removed the hyper-extension by a subcutaneous section of the extensor tendons of all the toes, with the exception of the two great toes. Resection of the first metatarsal head was made next, and, after the wound had healed, the fifth metatarsal head was also resected. For resection of the first metatarsal head, in this case, the bone-cutter was used; but the bone split, and there was in consequence a little more defect left than intended. The patient, however, after recovering from the wound, could use the foot perfectly; and having been previously prevented from serving as a waiter, on account of the deformed joints of the feet, he was so much pleased with the result of the operation that he asked to have his other foot also operated upon in the same manner. Unfortunately, circumstances did not permit his remaining in the hospital any longer, and he was discharged before the second operation could be performed.

The fourth and fifth cases are at the present time under treatment in the hospital.

No. 4, A. R., 50 years old, a dyer, was admitted January 19th, 1874, having hallux valgus of the right foot, complicated with caries of the joint. He was operated upon February 2d, 1874. Dr. Hamilton, who performed this and the next operation, wished to use the chain-saw. Unfortunately, however, this saw, the only one in the house, broke before the bone was cut through, and he resorted to the bone-cutter; and here happened the same accident mentioned in a previous case, namely, the splitting of the bone, leaving an unnecessarily large defect.

The fifth and last case, E. D., 19 years old, a carpenter, was admitted January 22d, 1874. He sought admittance only for a wound of a finger, caused by a circular saw. I discovered accidentally that he had abduction of both great toes. As he was unable to work at his trade, while the wound of the finger was under treatment, I proposed to him our operation of resection. Though his feet had not as yet seriously disabled him, as was the case with the other patients, he comprehended the advantage of my proposition, and submitted to the operation February 9th, 1874. This time deapitation was made by the chain-saw, and this proved preferable to the other instruments, as by its use the splitting of the bone, as well as injuring unnecessarily the soft parts, was avoided.

Our experience proves this operation to be free from danger, recovery having taken place in all the cases in a short time, through the use of the permanent warm-water bath.

The operation consists in making a short longitudinal incision over the projecting portion, down to the bone. The soft parts and tendons are raised from the surface of the bone, and the head is excised. For this purpose the chain-saw is to be preferred to the bone-cutter. The hemorrhage is usually slight, especially when Esmarch's bandage is used. In order to permit the free escape of the secretions, the wound is left open and the foot is placed—generally after 24 hours and sometimes sooner—in a water-bath having a temperature of 90° Fahr. After about two weeks the warm bath is replaced by warm-water fomentations. The wound rapidly fills up with granulations; the great toe, somewhat shorter, becomes straight without any assistance, and a firm tissue is formed at the point of resection between the toe and metatarsal bone, while the weight of the body can be well supported by the uninjured plantar surface. Suppuration

of the sheaths of the tendons has never occurred, and only in the one case of suppurative of the joint did we have a small circumscribed phlegmon and abscess on the dorsal surface of the foot, which, however, having been opened, speedily got well.

Amputation of the great toe has frequently been made for hallux valgus, but when amputation at the joint (exarticulation) is practised, a cicatrix usually remains on the head, which causes great pain when it receives the pressure of the boot; while amputation, including the head of the metatarsal bone, deprives the arch of the foot of an essential support.

In short, my experience in resection of the joint in cases of hallux valgus leads me to consider this operation preferable to amputation and to any form of orthopaedic treatment in old and extreme cases. I must, therefore, regard resection as a valuable addition to our surgical treatment of these unfortunate cases.

Résumé :

1. Resection of the head of the first metatarsal bone for abduction of the great toe is, according to our experience in St. Francis Hospital, a safe operation, when, as after-treatment, submersion in warm water is adopted.
2. Resection is equally safe as, and furnishes a more useful limb than, amputation.
3. Resection in old and obstinate cases of hallux valgus is to be preferred to orthopaedic appliances.
4. Finally, resection, properly made, leaves the limb without apparent mutilation, and in a condition as useful as the healthy and sound foot.

A FEW REMARKS ON THE TRANSFUSION OF BLOOD, WITH A MODIFICATION OF THE APPARATUS OF AVELING.

By B. E. FRYER, M.D.

SURGEON U. S. ARMY.

To show that the subject of transfusion is one which a large portion of the profession has not yet fully weighed the importance of, nor realized the fact that this measure can frequently be made applicable in cases which are now quietly otherwise yielded to death, we have only to call attention to the rarity of reported instances in which the operation has been taken advantage of, and to refer to the many obvious ones in which it should be made available. Even in threatening dissolution from the direct loss of blood,—such as from wounds of large vessels, from prolonged epistaxis, or, in probably one of the most frequent opportunities met with, from hemorrhage, post-partum, where the restoration of blood by transfusion has been, so to say, legitimized—but few of us are prepared for the emergency, or if prepared, do promptly act and give the then almost only chance for life.

We will briefly state the kind of cases in which it has occurred to us that transfusion should be had recourse to without hesitation, and they may be conveniently noted under two heads.

We would include in the *first* class those cases in which a copious blood-loss has occurred and immediate death is threatened. As is well known, it is in these mainly that the measure has been applied. It might well be tried in cases of injury accompanied by a more moderate hemorrhage, and where it is necessary to do an important surgical operation, and this operation is delayed (often disastrously) for a reaction by

ordinary means. Moreover, it should be done before or after necessary surgical measures in asthenic patients, in order to avert pyæmia and its allied evils, especially in operations where the peritoneum is involved. After labor, too, where hemorrhage may have been great, but not profuse enough to threaten immediate death, it should be done to avoid septicæmic difficulties. For that depression from loss of blood, etc., is a most direct cause of pyæmia and its pathological associates, those of us who have had to treat large numbers of gunshot and other injuries, and to operate in these cases where hemorrhage and other depressing causes had done sad havoc, well know.

But we have in the *second* class a larger number of cases—diseases both acute and chronic—and here we more commonly meet with opportunities. In such, transfusion has scarcely been thought of; but it is in these, too, it ought to be, and will be, we think, taken advantage of. Of the acute cases we refer to, those in which natural nutrition is for the time suspended, either from a direct lesion of the blood-making system in one or more of its divisions, or is indirectly affected in consequence of some profound systemic impression, where if we can but bridge over a short period by keeping life's machinery going, we may ultimately bring about a restoration of the healthy nutrition pro-

satisfactorily proved that milk may be safely and generally used in transfusion, and with the desired result, a great advance will be made in the matter, it being nearly always obtainable, while many of the difficulties and inconveniences in the use of blood will be avoided. A saline solution (such as that of Mr. Little *) should be tried to save life, if nothing else is at hand.

The instruments for transfusion are, as is well known, quite numerous, and while many of them are very good, we believe that of Aveling, for immediate transfusion, to be probably the simplest, safest, and most easy of application. We have lately modified it by adding another bulb to the tube, and by having both tube and bulbs cast of the rubber into one piece. By the additional bulb we can save time in doing the operation, and can keep the blood moving along the tube almost continuously. In having the tube and bulbs in one, we do away with the metal portion which couples them in Aveling's apparatus, and we thereby diminish the risk of the blood lodging and coagulating; while we can, if necessary, compress the whole apparatus more completely. As in Dr. Aveling's instrument, there are no valves. The inner wall of the whole apparatus is perfectly smooth, and we have had the opening from tube to bulbs made a gradual slope,

cess, and thus save life. To particularize: acute gastric troubles, giving excessive and continuous vomiting; acute diarrhoeas and dysenteries; in peritoneal inflammations, in some of the low forms of fevers where waste is excessive and the absorption of nourishment nil. In cholera it should be done more generally than it has been. It might be tried, too, in some of the acute diseases of young children, particularly in those which give convulsive movements and convulsions proper, and which often indicate to us the diminished blood-supply to the brain, and tell us that death may come before the return of the natural food absorption can again put the nerve-centres *quietly* at work.

In chronic cases where the blood-making is reduced or nearly destroyed, we might often prolong life by transfusion. Such cases are not frequent, though we need not enumerate them. We might well apply the measure even in some cases of phthisis pulmonalis.

In regard to the fluid to be transfused. As is well known, human blood is that to be most desired, after this the blood of some of the lower animals may be selected. Dr. Hodder, of Canada, threw into the veins of some of his cholera patients fresh milk, and with excellent results. The writer has experimented with milk injections in the veins of dogs, and though the experiments have not been completed as to a test of the nourishing effects of the milk so given, no bad symptoms have become apparent. If it can be

thus altogether doing away with corners in which the blood might be arrested and form a clot.

The instrument of Aveling is intended for immediate transfusion. We have added a glass vessel which can be fitted to the tube, and the whole then used as a mediate transfuser if desired. The accompanying cut gives a good representation of the apparatus.

The manner of using the instrument is very similar to Aveling's. The cannula marked B is placed in the giver's vein, that marked C in the vein of the receiver. The tube and bulbs having been filled with warm water, or, better, with Mr. Little's saline solution (also warm), are now adjusted to the canule and the blood allowed to flow into the apparatus. The canule being steadied by an assistant, the tube is to be nipped tightly between the fingers, close to the giver's or efferent end, and then the bulb marked 1 is to be compressed, and the blood of course forced on towards the receiver. While this bulb is still held compressed, the tube at the giver's side is to be relaxed, and that portion of it between the bulbs is to be nipped; bulb 1 is relaxed, and No. 2 compressed and held; then the tube at the receiver's side is to be seized and held to prevent re-gurgitation, and the whole apparatus allowed to refill. The same operation is to be repeated till sufficient blood

* Mr. Little's solution is composed of chloride of sodium, 60 grs.; chloride of potassium, 6 grs.; phosphate of soda, 3 grs.; carbonate of soda, 20 grs.; water, 20 ounces.

is transfused. As suggested by Dr. Aveling, a few drops of ammonia solution may be injected into the bulbs now and then, by a fine-pointed hypodermic syringe, in order to more effectually prevent coagulation. It will be found that considerable force is necessary in sending blood or other fluid into the veins. This we discovered while doing transfusion twice in a case after hemorrhage from gunshot injury, and we have also found it in our experiments on the lower animals. It is a fact we have not seen noted in connection with transfusion, and one well worth remembering.

In order to use the apparatus as a mediate transfuser, the vessel marked A in the cut receives the blood, the tube is to be applied, and the instrument used as before directed. If the blood is not defibrinated and strained, three or four drops of ammonia solution to each ounce are added, in order to avoid coagulation.

The instrument is made by Messrs. Tiemann & Co., 67 Chatham street.

We would suggest to those who may become interested in transfusion, that though the operation is a simple one, it requires care, and it should first be practised once or twice on the lower animals; no difficulty will then be had in doing it on man when occasion requires.

ARMY STAFF RANK.—BROOKLYN, N. Y., March 18, 1874.—At a regular meeting of the Medical Society of the County of Kings, held in the city of Brooklyn, March 17th, 1874, A. J. C. Skene, M.D., President of the Society, presiding, and R. M. Wyckoff, M.D., Secretary of the Society, acting as Secretary, on motion of Dr. E. R. Squibb, a member, the following preamble and resolutions, after being fully considered and discussed, were unanimously adopted by the Society, and ordered to be recorded on the minutes thereof, as follows:

Preamble and Resolutions of the Medical Society of the County of Kings.

Whereas, The American Medical Association, and the Medical Society of the State of New York, as well as other medical organizations throughout the United States, have earnestly and urgently memorialized Congress to place the medical corps of the army upon the same footing in regard to rank, pay, and promotion with the medical corps of the navy, and with other staff corps;

Therefore be it resolved, That the Medical Society of the County of Kings, believing the views expressed in the memorial of the American Medical Association to be wise and just, and for the best interests of the Government, heartily endorses them, and joins in requesting Congress to remedy the injustice under which the medical corps of the army now rests.

Resolved, That a copy of this preamble and these resolutions, properly attested by the seal of the Society and by the signatures of the President and Secretary, be sent to each of the senators of this State, and each of the Representatives of this District, in the present Congress.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, April 15, 1874.

THE REORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

It is now pretty well conceded by all who have given any attention to the subject that the American Medical Association has been steadily losing ground for the past few years in the estimation of the profession of the country, and that some change in its organization is demanded to make it what it should be, the representative medical society of the entire country. We have on former occasions suggested the means to this end, and now, on the eve of another meeting, we seize the opportunity to refer to them again.

In the first place, we contend that the discussion of ethical questions and the detailed transaction of miscellaneous business of all kinds should, as far as possible, be kept out of the public meetings of the Association. At almost every meeting, test-questions of ethics are thrust upon the Association for its consideration, and generally there is a scene which is as disgraceful as it is unnecessary. The discussion is for the most part limited to a few interested parties, who take opposite sides and vie with each other in maintaining the reputation of the Association as a quarrelsome and undignified body. It is almost solely on this account that it has lost its influence with the profession and the public, and unless some change of its organization is effected, having for its object the prevention of further family quarrels, the Association must either disband or die of inanition. One or the other of these results is inevitable. The way to separate the legislative or judiciary element from scientific element, is to have all matters pertaining to the former referred to a committee. It is highly important that this committee be large and composed of men who have the confidence and respect of the profession at large. Their judgment upon any point should be final, or at least, in case of marked disagreement, a

majority and minority report should be presented, and the vote of the Association upon either should be considered conclusive. If it be necessary to have any discussion upon the subject, it should take place before the committee, and not in open meeting. It has been suggested that this committee should consist of at least twenty members, who should be proposed by the nominating committee and elected by a vote of the Association. It is important to have this committee a large one, in order that it may be representative of the whole country, one or more members being elected from each State represented at the meeting. This arrangement would make the formation of sectional rings in the council impossible.

At the last meeting in St. Louis, Dr. Davis made some propositions for the creation of this committee, but they were laid upon the table. Sufficient time has now elapsed, since their presentation, to prepare the members to vote intelligently upon them, when the matter shall be again considered. We hope that the mover of this resolution will not fail to call them from the table at Detroit, and that every friend of the Association who may be present may be prepared to act upon it, and give him all the aid and countenance which the importance of the subject demands. So much, then, for the purely business element of the Association.

Another necessary reform is in the election of delegates. We have often alluded to the cheapness of delegateship to this Association, the question in the choice being not so much who shall go, as who will go, to the next meeting. The consequence has been that the majority of the really good men stay at home and leave the discussion of topics which concern the present and future welfare of the Association to incompetent bunglers and inconsiderate meddlers. We want more stringent rules established for the election of these delegates. Their choice should be restricted to the county societies principally, and the colleges and other similar institutions should be left out of consideration entirely. By the exercise of due care in this regard, it will by and by be considered an honor to be chosen, and our best men may deem it worth their while to enter the lists on that account.

Another way of developing an interest in the Association on the part of the best medical men in the country, would be to give more prominence to the scientific element. In the first place, we prepare ourselves to do this by narrowing the discussion of the strictly business matters to a council, as already stated, and give all the spare time to scientific medicine proper. In the second place, we should develop the resources of the various sections. An experiment in this direction is to be tried at the next meeting by having phonographic reports of these sections printed in slips for the members on the morning after the respective meetings are held. We believe that this plan will tend to simplify the working of the scientific machinery,

and will not fail to be productive of great good to all parties concerned. By these means a member can not only attend his favorite section, but have the great advantage of knowing what has been done in all the others. In this connection we may mention that the rule will be established to have all lengthy papers presented in abstract, and then referred to the committee of publication, who have absolute power to accept or reject said papers solely on the ground of merit.

The suggestion of Prof. Gross, to have annual addresses on medicine and surgery, delivered in open session, by gentlemen selected by the president, is a timely one, and deserves more consideration than it received at the last meeting. These could take the place of the tedious reports on medical education, climatology, and medical literature, and would doubtless be well received by all.

Whatever we may do in our attempts to systematize the scientific work, it will avail nothing if a change is not made in the business management. It is not only useless to postpone definite action upon this matter, but eminently hazardous. The longer the procrastination, the greater the danger of an explosion, in the shape of another disgraceful scene. This disaster must come some time or another, and may be the death-blow of the Association. We trust that the physicians in Detroit will take this subject in hand, and signalize the coming meeting by one grand and determined effort to make the Association worthy of its name.

Reviews and Notices of Books.

A UNIVERSAL FORMULARY: Containing the Methods of Preparing and Administering Official and other Medicines, the whole adapted to Physicians and Pharmacists. By R. EGLEFIELD GRIFFITH, M.D. Third Edition, carefully revised and much enlarged, by John Maisch, Phar. D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. With Illustrations. Philadelphia: Henry C. Lea, 1874. pp. 779.

THE FORMULARY, having been for more than twenty years a familiar occupant of the physician's library, has long established its claim to practical usefulness. Though perhaps more especially adapted to the wants of the pharmacist, the prescriber finds here convenient access to a variety of valuable preparations and formulae not afforded by the books of *materia medica* in ordinary use. A new edition was, however, much needed, and that the requirements have been competently met the eminent name of its editor is sufficient guarantee. Various improvements are manifest, which the marked increase in the number of pages by no means wholly represents. Perhaps their value to the physician might have been still more enhanced had some of the foreign hospital pharmacopœias been incorporated, such as the Throat Hospital Pharmacopœia of Morell Mackenzie, in London, or the *Wiener Rezept Taschenbuch* of Vienna. This, however, would very likely have unduly increased the bulk of the book, and a satisfactory selection from these works would undoubtedly be an exceedingly delicate task. The pharmacopœias of Great Britain, France, and Germany have received due attention.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 14, 1874.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

MORBUS COXARIUS—OPERATION.

DR. SAYRE presented the remaining portions of the head and neck, and a portion of the trochanter, which had been removed from the femur of a girl *æt.* 12. The operation was performed at Charity Hospital, Nov. 1, 1873. The patient received an injury three years previous to the operation, and the case presented the ordinary history of morbus coxarius. When the operation was performed it was found that the head and neck of the bone had been almost completely absorbed, and the acetabulum had been perforated. The limb was dressed in the wire-breeches, and the child placed in bed. At the time of the operation the patient was in a very precarious condition, having suffered from extensive suppuration and exhausting discharge. She, however, made a most extraordinary and rapid recovery. On the 10th December small spicule of bone, from the size of a pin's head to that of a pea, escaped from a sinus. The child is now running around in the ward of the hospital, has free motion of the limb, and can bear the weight of the body upon it very well. There was only a moderate amount of shortening.

A second specimen was presented by Dr. Sayre which was taken from the hip of a lad eight years of age, and a Dane by birth. No knowledge of his previous history could be obtained. When first seen, the left thigh was strongly flexed, with the knee above the umbilicus; it was also strongly adducted, sufficiently so to carry the knee over to the opposite side of the body. Behind the trochanter were open sinuses, and through these dead bone could be felt. There was some difficulty in determining whether the present condition of the limb was the result of fracture, or diastasis, or was due to the exhaustive discharge, contractions, etc., incident to a somewhat prolonged course of hip-disease. The latter appeared improbable, judging from the appearance of the patient. The position of the limb, however, was evidently one that could not be obtained except the head and neck of the bone were separated from the shaft. Upon cutting down to the bone, it was found that the head and neck were both entirely gone, and the acetabulum was filled with new material. The general condition was an unusually good one, and, as has been suggested, contraindicated the existence of hip-disease. The reason for this was that the openings in the hip, from which the discharge took place, were so situated and shaped as to give complete drainage during the entire progress of the disease, thus protecting the patient from the irritating and exhausting effects of the presence and discharge of large quantities of pus. The bone was excised between the two trochanters, and was the specimen presented. Upon the inner aspect of the portion of bone removed there was an appearance indicating that new cartilage had been formed at that point. The specimen had been submitted to Dr. John J. Mason, for microscopical examination, and he reported that the portion alluded to was cartilage containing regular and fully developed cartilage cells. The practical point in this connection was that new cartilage could be developed in these cases, within one-fourth of an inch of diseased bone. Whether new cartilage is formed or not,

at the extremity of the femur, in such cases, the doctor was not able to say, for the pleasing reason that the patients did not furnish opportunities for post-mortems.

LUXATION OF ELBOW-JOINT BACKWARDS, THREE WEEKS' STANDING.

DR. SAYRE also made a few remarks of a practical nature with regard to reduction of an elbow-joint which had been dislocated backwards. It was well known that luxation of that joint backwards was very difficult of reduction unless the operation was done immediately after the accident. A man came to his office who had been suffering from this form of luxation for about three weeks. Several attempts had been made at reduction, and failed. A Jarvis adjuster had been employed, and the instrument had been broken by the force expended upon it. It was thought highly probable that division of tendons would be necessitated before reduction could be effected; but it was decided to make one more effort, before the operation was resorted to. The man was strong and well developed. For the purpose of making extension the hand of the patient was introduced into a hollow piece of elastic basket-work, which would act after the same manner as what is known as the Indian puzzle; the more traction there is made upon the distal extremity, the firmer was the hold upon the hand. Counter-extension was made by a sheet passing through the axillary space and attached above. Traction was then made, gradually bringing the arm into the straight position.

When the straight position had been obtained, the elbow was bent firmly forwards for the purpose of lifting the coronoid process of the ulna from the intercondylar fossa, and when it was thought that the coronoid process was sufficiently removed from the fossa, sudden and forcible flexion of the arm was made, and the bone came into place.

DR. FINNELL inquired with regard to the proper time, during the progress of a case of hip-disease, for the performance of the operation of excision.

DR. SAYRE replied that the operation should be performed as soon as the bone was found to be uncovered of its cartilage and caries was present.

CANCER OF STOMACH, LIVER, AND PLEURA.

DR. LOOMIS presented four specimens of cancer taken from the body of an Englishman *æt.* 73 years, who was admitted to Bellevue Hospital, December 1, 1873. The man had no hereditary, neither was there any history of either specific rheumatic disease. He had been perfectly healthy until about three years previous to his admission to the hospital. At that time he was confined to his bed with some severe illness, the exact nature of which could not be determined. The prominent symptoms, however, were edema of the feet, slight disturbances of vision, hemi-crania, and pain in the back. He recovered from that sickness sufficiently to permit him to engage in his ordinary labor, but he said that he had never felt perfectly well from that time.

About two months previous to his admission he noticed that he was losing flesh and strength, and suffered somewhat from pain in the upper portion of the abdomen, although he was unable to give that pain a precise location. He also suffered from loss of appetite, but at no time suffered from vomiting. Six weeks before his admission to the hospital he noticed a tumor, which was situated in the central portion of the abdomen, and he also noticed that, when pressure was made upon the tumor, it gave him pain. There was

no pain, however, independent of the pressure. He also noticed that at the same time he was becoming very weak, and that his weakness increased with the increasing size of the tumor. He was compelled to enter the hospital simply because he was unable to even walk about in the streets without assistance. At the time of his admission he was extremely anemic. There was none of that dingy hue of countenance present which was ordinarily seen in connection with malignant disease, nor was the patient extremely emaciated. He only complained of pain in the upper portion of the abdomen and over the pit of the stomach, but at no time during his suffering from the disease had he suffered from nausea and vomiting.

Physical exploration of the chest revealed a circumscribed friction-sound at the left posterior and upper portion of the chest. There were no cardiac murmurs, except a murmur heard above the base of the heart, which was regarded as anemic in character.

Physical exploration of the abdomen revealed by inspection the existence of a tumor situated in the median line extending upwards from a little above the umbilicus to the xiphoid cartilage. By percussion the tumor was distinctly recognized as extending from one inch above the xiphoid cartilage downwards to about one inch above the umbilicus, in the median line. Percussion, dullness, upon the right side anterior, extended from one inch below the nipple to three inches below the free border of the ribs. The region of dullness represented in the central portion of the abdomen was continuous with the line of hepatic dullness, and extended to the left beyond the free margin of the ribs. The dullness was evidently due to the presence of a solid tumor. The mass had a firm, uneven, nodulated feel, and diagnosis of cancer of the liver was made. Cancer of the stomach was rejected on account of the absence of gastric symptoms. From this time the patient went on suffering more and more pain, becoming more and more exhausted, and died on the 28th of December, as the direct result of exhaustion.

Autopsy.—Corresponding to the point at which the friction-sound was heard, was found a small mass of sub-pleural cancerous growth. The walls of the left ventricle of the heart were, perhaps, slightly hypertrophied. The right ventricle was dilated. The aorta, from its origin to the commencement of the descending portion, was extensively atheromatous. The liver was found to be twice its natural size, and the enlargement was equal in all directions. The surface of the organ was covered with nodules varying in size, form, and presenting a variety of colors, varying from an almost white to a tawny slate-color. Upon section the organ showed unmistakable evidences of the presence of cancerous growths. Almost the entire substance of the organ was involved, yet the patient had no jaundice during life. There were no evidences of cancer of the liver at any time, except the pain and enlargement.

The stomach was found distended, and, upon opening it, there was at the pyloric orifice and in the lesser curvature a large development of cancerous growth. The pylorus was constricted, but there were no ulcerations of the surface above the cancerous development. The interesting feature in this connection was the existence of extensive cancerous growth in the stomach, without any of the ordinary symptoms which attend such developments. The extent and character of the development in this case were believed to leave but little doubt but that the primary origin of the cancerous growth was in the stomach.

Upon the walls of the bladder there were noticed

some nodules of cancerous growth, which were sub-peritoneal. Some of the mesenteric glands were enlarged by cancerous outgrowths, and one of the bronchial glands was also enlarged, and the enlargement was probably of a cancerous nature. There was, therefore, primary cancer of the stomach, and secondary cancer of the liver, and secondary cancerous growth beneath the pleura and also beneath the peritoneum covering the bladder. The kidneys presented evidences of the existence of interstitial nephritis, which possibly accounted for the attack he had three years ago.

Dr. SAYRE remarked that there must have remained sufficient healthy liver-tissue to perform the normal functions of the organ, else there would have been a development of jaundice during life.

Dr. LOOMIS remarked that as a rule, unless cancerous growth was developed in such a measure as to cause pressure upon the transverse fissure of the liver, thereby causing obstruction to the ducts, jaundice was not necessarily present.

Dr. O'SULLIVAN recalled the history of a case from which he had presented a pathological specimen in 1862. The specimen was one of extensive enlargement of the liver from cancerous growth. The patient lived about eighteen months after the first appearance of the tumor. There was no great amount of emaciation present, and the patient retained food to the very last. The case was recalled simply to illustrate that even large tumors which press upon the diaphragm, stomach, and aorta, and produce, as would be expected at least, more or less of irritation, sometimes do not produce any gastric symptoms whatever.

Dr. FINNELL remarked that so far as the symptom of pain was concerned in connection with cancerous growth, it was extremely unreliable. It may or it may not be present. He had very often found well-developed cancerous growths in the stomach at post-mortem where no symptoms other than those attending an ordinary dyspepsia had been present during life.

ENCYSTED TUBERCULAR MASS.

Dr. FINNELL presented a specimen which he regarded as an encysted mass of tubercular disease, which had been removed from the lower lobe of the right lung. The mass was about the size of an ordinary almond. The specimen had not been examined microscopically. There were no nodules of like character found at the apex. The specimen illustrated one point, namely, that tubercular masses may be found in the lungs of individuals who have died, having their lungs in an otherwise perfectly healthy condition. It had been the doctor's experience to find such developments in about one in ten persons.

Dr. LOOMIS remarked that the specimen had a decided appearance of an infarction of the lung which had become encysted.

PLEURISY, EMPYEMA, AND CARNIFIED LUNG—A QUESTION OF DIAGNOSIS.

Dr. LEWIS SMITH presented a specimen of carnified lung taken from the body of a child thirteen months old. The history of the case was as follows:

The child had suffered from cough for several months, accompanied by more or less of febrile excitement. The sickness had been regarded by the attending physician as being due to malarial poisoning. The doctor saw the child but once, and at that time was able to recognize the presence of pleurisy.

At post-mortem all the organs of the trunk were in a healthy condition, with the exception of the right lung, which was found in the carnified condition there seen.

The anterior portion of the lung was adherent to

the walls of the chest as far around as the axillary region, and from this point to the sternum the organ was crowded upwards by pus which accumulated to about three ounces in quantity. The case was regarded as one of much interest, for the reason that the occurrence of pleurisy in infants is not infrequent, and the occurrence of empyema is much more frequent than is generally supposed. There is some difficulty in diagnosis when serum or pus is present in the pleural cavity of a young child, for the reason that bronchial respiration and vesicular respiration are conveyed from the opposite side of the chest, which may, and frequently does, lead to the error of regarding the case as one of pneumonia; and if the case proves fatal, and no post-mortem is obtained, it is very commonly supposed that the development of tubercles has caused the death of the child. Pus is very often found in the pleural cavities of children at post-mortem, in cases where pleurisy had not been diagnosed. Pneumonia, and, as was the case in the present instance, remittent fever, are very frequently mistaken for pleurisy.

Among the doubtful cases, whenever there is perfect flatness upon percussion, perhaps in nine out of ten, there is pleuritic exudation. It is very easy, however, to determine the nature of the disease by the use of the hypodermic syringe. As illustrated in the present case, the point at which the needle should be inserted is of some interest, showing that it should be a little below the angle of the scapula, if wounding the lung would be avoided.

When the presence of pus is determined, a free opening is made through the chest-walls, and in most instances the child begins to improve from the time of the operation.

Dr. LOOMIS remarked, with regard to differential diagnosis in the class of cases alluded to by Dr. Smith, that it would seem unnecessary that mistakes in diagnosis should be made; for practising vocal fremitus would at once settle the question. With regard to treatment, Dr. Loomis also remarked that he had within the last eight months successfully treated three such cases by means of the aspirator, removing a greater or less quantity of fluid from the pleural cavity, every third or fourth day, according to circumstances. This method was regarded as preferable to the free incision through the chest-walls.

Dr. SMITH remarked, with regard to the use of the aspirator, that he had employed the smallest sized needle, and the size next larger, and was not able to remove the fluid through them. He did not regard the admission of air into the pleural cavity as being anything especially detrimental.

Dr. LOOMIS remarked that the only objection to the admission of air under such circumstances was the liability to the development of gangrene of the lungs.

Dr. FINNELL inquired of Doctors Smith and Loomis if they were cognizant of any cases of empyema that had recovered, whether in children or adults, when treated by removal of the pus through a free incision in the chest-walls?

Dr. SMITH replied that, among children, he could refer to several cases of complete recovery.

Dr. SAYRE mentioned a case that he had treated several years ago, in this manner, and his patient completely recovered.

Dr. LOOMIS remarked that he had never resorted to free incision through the chest-walls; but that he had drawn from the chest of a boy seven years of age as high in the aggregate as twenty-five ounces of pus, by means of the aspirator, and the patient was now perfectly well.

GLIOMA RETINÆ.

DR. H. KNAPP exhibited an eyeball, with the following remarks:

The specimen was kindly sent me for examination by Dr. J. THOMPSON, of Indianapolis. It was taken from a girl, *et.* 1 year, who was brought to the doctor with all the symptoms of the so-called "*Beer's anurotic cat's eye*." He declared the disease glioma of the retina, and urged the necessity of the immediate removal of the eye, to which the parents consented. He learned that a brother of the babe had died from the same disease when he was $2\frac{1}{2}$ years of age. A cousin of the patient on the father's side had died from the same disease in his second year. The father's aunt lost two children between their second and fourth years of age, whose eyes were said to be affected precisely in the same manner.

The extirpated eyeball showed a soft, granular tumor, springing from the outer face of the totally detached retina, occupying about one third of the cavity of the eye. In addition to this larger tumor, there were several smaller, flat and nodular growths, of the same appearance, in different places on the outer surface of the retina. All the tumors consisted of small round cells embedded in a scant matrix, and of many thin-walled blood-vessels. Sections through the smallest tumors and the adjacent retina discovered that the pseudoplasia originated in the inner granular layer of the retina. There were in this layer circumscribed accumulations of small round cells forming a globular intumescence, raising the outer granular and bacillar layers, ultimately perforating them, and expanding in the space between the detached retina and the choroid.

The case is distinguished, *clinically*, by the novel feature of a family predisposition to glioma—the encephaloid cancer of earlier authors—of the retina which, as is now well known, is met with in children alone. Life can be preserved only by the early extirpation of the eyeball. The patient from whom this specimen was taken has continued in good general health, and when last seen, five months after the operation, had no symptom of a relapse. *Microscopically* the case is distinguished by the clearness with which the origin of so malignant a growth could be traced to one layer of the retina.

The Society then adjourned.

Stated Meeting, January 28, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

THROMBUS OF THE PULMONARY ARTERY.

DR. F. D. LENTE presented a specimen of heart and annexa removed from a female patient, aged sixty-two, who had been injured on New Year's day while sleigh-riding. The cause of the accident was the breaking of a runner which precipitated the patient and her companions to the ground. When picked up, she was found jammed between two rocks with a fracture of the tibia into the knee-joint; at the same time one of the sleigh seats was lying across her chest.

Dr. Lente saw her within an hour after the accident, when she complained for the most part of a severe pain in the breast. The fracture was at once placed in an immovable apparatus and did well. The only sign of injury to the sternum was an ecchymosis, which increased during the time that she lived. The complaint of pain of the breast was constant, the patient affirming that she had suffered some internal injury at the time of the accident. Between the second and third week she complained of severe neuralgic pains, which continued more or less up to the time of her

death. For these pains hypodermic injections of morphine were administered.

On January 24, the third week of the attack, very alarming symptoms suddenly set in, and during Dr. Lente's absence Dr. Murdock was called in, who found the patient suffering from nausea, intense headache, pains in different parts of the body, with the face perfectly blanched, and a pulse scarcely perceptible. He commenced stimulating the patient in every possible way. He gave hypodermic injections of brandy (15 minims) every fifteen minutes, and also administered morphine hypodermically for the control of the neuralgia. She had no dysphagia nor dyspnea, and complained principally of excessive weakness. Dr. L. saw her at 5 P.M., when she was said to be rallied somewhat. She had not vomited any, and was perfectly sensible. Complaining at the time of pain across the abdomen and right ankle, an hypodermic injection of morphine was administered, and from this time until her death she did not suffer from severe pain. Despite all the efforts used, among which was the use of the faradic current, she sank, and died at 8 o'clock P.M. The diagnosis of thrombus of the pulmonary artery was made out previous to death.

At the autopsy there was nothing worthy of note in the chest contents, save the heart and its surroundings. The heart itself was well covered with adipose tissue. On opening the right ventricle it was found to contain a moderate amount of fluid-blood, and also a large firm clot passing directly through the auriculo-ventricular opening, and firmly attached to the columnæ carneæ on one side, and the musculla tendinea on the other. On slitting up the pulmonary artery it was found that the thrombus completely stopped up the vessel on the left side, and left only a small passage for the blood on the right. The clot could be traced for two inches through the ramifications.

In conclusion, Dr. Lente remarked that the specimen explained why the symptoms so closely resembled those of internal hemorrhage. No connection was made out between the accident and the direct cause of death. The valves of the heart were perfectly healthy.

STRICTURE OF THE RECTUM—LUMBAR COLOTOMY.

DR. E. MASON presented a portion of the colon taken from a patient in Roosevelt Hospital, who had suffered for a long time from stricture of the rectum, and for the relief of which colotomy had been performed.

The patient first entered the hospital February 15, 1872, being then seventy-six years of age. Two and a half years before, he had suffered from a severe attack of dysentery, and six months after he recovered therefrom, he was seized with a severe pain in the bowels, which would recur at intervals for months afterwards. During December of that year a severe hemorrhage occurred per rectum, and for weeks this also continued to recur when there was any straining at stool. From this time also the pain, which he located in the middle of the sacrum and down the thighs, continued to increase, and a difficulty in defecating showed itself.

Upon examining the patient when he came into the hospital, a tight annular stricture, with some induration of the bowel, was discovered, three and a half inches from the anus. There was also some ulceration of the bowel below the stricture, and there was also a probability of the same condition existing above the constriction. The pains in the sacrum of which he complained were intense. His gait was very peculiar—he would straddle, and, partly stooping, would step lightly, as if he were carrying some heavy weight in the pelvis. The stricture admitted the tip of the little finger.

The treatment consisted in nourishing diet, and the gradual introduction of bougies. The latter he bore very well for a time, but the pain became intense and hemorrhage began to occur whenever the stricture was touched. Sometimes these hemorrhages were so severe that injections and suppositories containing persulphate of iron had to be employed. The stricture began to show a tendency for closing fast, and the patient complaining of severe lancinating pains all through the pelvis, the suspicion that the disease was cancerous was apparently well founded. On consultation it was concluded to perform lumbar colotomy as the only means of affording relief. This operation was done, opening the colon on the left side, on the 26th of June, 1872. The patient recovered very nicely from the operation, and was relieved of the different symptoms from which he had suffered. This condition continued for some months. At times, however, he would have a recurrence of the pain, which he located across the diaphragm, and would also complain of the dragging pains in the vicinity of the sacrum. These paroxysms would continue for a few days only at a time. As is usual after the operation of colotomy, the stricture began to give, and the ulcers below it began to heal. After a while, in the hope that the passage of fecal matter per rectum might be made clear again, and the fistula healed, bougies were again passed, but the pain soon returned and their passage had to be abandoned. An examination at this time showed little or no stricture present. The idea of malignancy was then given up, and attention was directed to the possibility of the existence of another stricture higher up, probably in the vicinity of the transverse colon; this possibility was confirmed by the arrest of an oesophageal bougie after it had been passed for a short distance upwards through the artificial opening.

When Dr. Mason again came on duty, in December, he found the patient in very much the same condition. The symptoms of rectal stricture having disappeared to a great degree, he made an attempt to heal the artificial opening in the hope that the feces might escape *per vias naturales*. For this purpose a plug was placed over the opening and kept there for a time, during which there occurred one or two natural passages. The pain, however, became so excessive that the pad had to be removed. Just after this he began to suffer from difficult micturition. He continued to grow weaker and weaker, and took to his bed, from which he never arose. The diarrhoea, which had existed for a little while before, gradually increased, and his urine had to be drawn off with the catheter. He died January 27, living one year seven months and a day from the time of the operation.

Autopsy.—On account of the extreme difficulty of obtaining a post-mortem, only a portion of the colon, including the rectum, also the bladder, were removed en masse through a small opening in the abdominal walls. Dr. Lingard, who made the examination, stated to Dr. M. that the small intestines were free, and that there were no signs of peritonitis in the neighborhood of the operation, but on the right side there were marks of old adhesions where the caput coli was bound down, and higher up the same kind of bands made the stricture in the transverse colon which was recognized during life.

The bladder walls were thickened and showed cystitis. The rectum presented little or no traces of ulceration, and little or no traces of stricture. Around the stricture, outside the gut, the tissues were considerably indented. Just above the stricture were to be seen the marks of ulceration extending along

the sigmoid flexure, and up to the point of the operation. The transverse colon was constricted by bands, as before stated, and in the vicinity of the caput coli there was a third stricture with the edges ulcerated, while the surrounding mucous membrane was considerably thickened, and the neighboring mesenteric glands much enlarged. The mucous membrane of the colon was in several spots intensely congested.

Dr. LENTE remarked that he had seen this case before the operation, when the stricture was very firm, and barely admitted the end of the finger. It was one of those cases which would have been diagnosed cancerous without any hesitation. He asked, in view of the attenuated and contracted condition of the intestine, if it would not be vain to expect that the rectum could ever again take on its legitimate function.

Dr. MASON replied he thought it was worthy a trial, although he was not aware that any such attempt had been successful.

Dr. SEIL remarked that Wood, of London, had succeeded in one such case.

RODENT ULCER OF EYELIDS. EPITHELIAL CANCER. SMALLER TUMORS ON OTHER PARTS OF FACE, AND A LARGER ONE ON LOWER JAW.

Dr. H. KNAPP presented a specimen and the patient from whom it was taken, and added the following remarks: This patient, an unmarried woman of 29 years of age, first noticed, ten years ago, a small wart-like elevation on the skin under the inner canthus of the right eye. It grew very slowly, was not influenced by internal remedies, but increased more rapidly by the local application of caustics. Three weeks ago, when I saw the patient for the first time, it presented the character of a rodent ulcer, occupying the region of the right lachrymal sac, extending 3" upward, and 9" downward, beyond the middle of the lower lid, leaving intact, however, the edge of the lid outward from a point near the lower lachrymal punctum. Its border was elevated, nodular, and ragged, its surface exulcerated, red, uneven. Several small nodes were in different places of the face; the two most conspicuous were pigmented, and situated, the one on the forehead and the other on the edge of the left lower lid. Besides, there was a tumor on the left side of the lower jaw, springing from the bone, with a ragged, hard periphery. The patient was in good health, and showed no symptoms of a constitutional taint. The question was: Is the disease lupus or epithelial cancer? I thought that the appearance of the pseudoplasms in the skin was that of epithelioma, but the patient was rather young for a carcinomatous disease. Dr. Sands saw her in consultation, and concurred with me in the opinion that the tumor of the lower jaw probably was a sarcoma with osseous spicules.

Two weeks ago I removed the pseudoplasm on the eyelids, and covered the defect by a flap taken from the forehead. The result of this blepharoplasty, as you see, is very satisfactory. The flap united to the wound in its whole extent, and the movements and closure of the lids are perfect.

Microscopic examination of the specimen discovered the structure of epithelial cancer. Epithelial cells, arranged in cone-like figures, separated by fibrillous tissue in which numerous small round cells are embedded, form the prevailing and almost exclusive parts of the pseudoplasm. The small tumor on the edge of the other lid had the same structure, with additional irregular pigment-cells. Dr. Sands will remove the tumor of the jaw, and I am anxious to learn of what nature it will be.

Dr. SELL remarked that he had witnessed an operation by Mr. Bryant, of London, for removal of a growth from the forehead of a boy, similar to the one upon the jaw in Dr. Knapp's case. In that instance, the roof of one of the orbits being involved, necessitating the removal of the same, the patient became blind in consequence.

Dr. KNAPP remarked that such tumors were not uncommon in the neighborhood of the orbit.

Dr. LENTE asked if in Mr. Bryant's case the blindness might not have been due to the necessary injury of the supra-orbital nerve in the operation. He himself has collected several cases bearing upon this point, and published them some years ago, having had his attention drawn to the subject by one he had while interne in the New York Hospital, in which blindness of one eye was due to the embedding of a fragment of a percussion-cap over the supra-orbital nerve, and as the result of the removal of said foreign body, the sight was perfectly restored.

Dr. HINTON remarked that in the treatment of epithelia of the orbit he had found marked benefit if not an arrest of the disease from the topical application of nitric acid, and cited two cases in point.

Dr. MASON concurred in this view.

Dr. KNAPP was of the opinion that after the disease had progressed to a certain extent, the knife was the only safe and reliable means of removal.

Dr. LENTE thought that such wounds after operation should be treated by electrolysis, as recommended by the electricians.

Stated Meeting, February 11, 1874.

Dr. H. KNAPP, PRESIDENT, in the Chair.

PRODUCED ABORTION—THE AGE OF A CORPUS LUTEUM.

Dr. FINNELL presented the uterus of an unmarried girl, aged sixteen, who died after a ten days' illness of peritonitis, the result of a produced abortion. She had been living for some time in the family of a physician, who suspiciously falsified the cause of death, when the case fell into the hands of the Coroner. The physician in question had given the death-certificate of pneumonia, and persisted in its correctness for a long time, in spite of the fact that at the autopsy none of the characteristic lesions of that disease were present. The body of the uterus was found very much enlarged, had a roughened mucous membrane internally, associated with which condition was a corpus luteum of three or four months' development. The case was "brought in" as one of abortion, and the physician was held to answer.

Dr. DOUGHERTY asked if any of the villi of the chorion were discoverable by a microscopical examination.

Dr. FINNELL answered that no microscopic examination had yet been made.

Dr. SELL remarked that he had recently read of a case in which the possibility of pregnancy could not be entertained, but in which an old corpus luteum was found in the ovary.

Dr. FINNELL thought such a case could be easily explained by assuming that the corpus luteum in question was one of menstruation.

Dr. JACOBI. What was the diameter of this corpus luteum?

Dr. FINNELL. About six lines.

Dr. DOUGHERTY referred in detail to a case of induced abortion, upon which he was called to testify as an expert. The uterus measured four inches in length, had an extremely patulous os, and presented a roughened surface internally. An examination of the

latter under the microscope showed beautiful specimens of the villi of the chorion; upon which fact he centred his opinion in favor of previous pregnancy. In that case the experts for the defence testified that it was impossible to tell the difference, under the microscope, between the villi of the chorion and the appearances of an ordinary dysmenorrhœic membrane.

Dr. JACOBI remarked that the finding of the villi settled the question, as there was no possibility of mistaking them for the pseudo-membrane. Dr. Finnell's history was not, however, complete without a microscopic examination, as otherwise the jury could not judge of the real merits of the case. As far as the corpus luteum of pregnancy was concerned, there was only one reason to favor the idea of pregnancy, and that was the size of the corpus explained by the natural condition of continued congestion favoring the growth.

Dr. DOUGHERTY presented two specimens of calculi for which he performed lithotomy, and gave a detailed history of each.

NASAL POLYPUS—A NEW METHOD OF EXTRACTION.

Dr. KEYES exhibited a young man upon whom he had operated for the extraction of a nasal polypus (myxoma). The growth commenced, seven years before, in the right nostril, and continued to increase gradually for four years, at the end of which time it was extracted by means of the polypus forceps. No relief followed; and the tumor, which evidently had not been extracted entire, continued to increase, and three weeks ago the patient consulted Dr. Keyes. The right nostril was then entirely occluded, and there was considerable deformity on the external aspect of the nose. An attempt was made to find the pedicle by the use of a probe, but without success. It seemed to be high up, and very long. Extraction with the long forceps was done, and as much of the tumor as could be reached was torn away. No relief followed. It was then discovered that a large remaining portion of the tumor was situated in the posterior nares. The patient being etherized, the forefinger of the left hand was introduced its whole length into the right nostril, which was unusually small and very dilatable. The forefinger of the right hand was then introduced into the mouth; the tumor, which was already well pushed back, was easily hooked backwards, and removed entire. The attachment was found high up on left side. The polypus itself contained in its substance two cavities of pus.

The interest of the case consisted in the felicitous method of operating, and in the apparent *a priori* impossibility of introducing a moderately large finger with such ease into a very small nostril.

In reply to a question from Dr. Knapp, as to whether the method of operating was original, he remarked that he had obtained the idea from Prof. Frank Hamilton, who had been accustomed to employ a similar procedure in such cases.

Dr. SELL remarked that Prof. Billroth performs the same kind of operation.

TUMOR OF ABDOMEN.

Dr. HALL presented specimens of the first portion of the colon, taken from a woman, aged forty-five, who was admitted into Charity Hospital last April. Four or five years before she noticed a tumor growing in the left iliac fossa, and tender on pressure. In the course of a year afterwards her health began to break down, and finally she became so ill that she had to seek admission into the hospital. At that time she was very much emaciated, complained of considerable pain in the

affected side, also of an obstinate diarrhoea alternating with constipation. She died early in January. The autopsy revealed a large tumor in the abdomen, which was bound down to the mesentery, and through which the first portion of the colon seemed to pass. It was pressing upon the external iliac artery and vein of the right side, causing an oedema of the corresponding leg. At the point of greatest pressure clots in the vein were discovered. The portion of gut passing through the tumor seemed to be perfectly healthy.

Dr. HALL presented a second specimen, removed from a woman, an habitual drinker for many years; was admitted into Charity Hospital very much broken down, and complaining for the most part of pain over the liver. She died soon after, and the diagnosis had been cirrhosis.

INFILTRATED CANCER OF THE LIVER.

At the autopsy the left ventricle of the heart was much enlarged, and pus was contained in the bronchi. With the exception of the liver, all the abdominal organs were found healthy. In the substance of the right lobe of the organ in question was an even and circumscribed infiltration of cancerous material. No other deposits were found in this or any other organ examined, and no evidence of the existence of this infiltration was given upon the surface of the liver. The tissue of this organ presented the gross appearances of a normal condition.

Stated Meeting, March 11, 1874.

Dr. H. KNAPP, PRESIDENT, in the Chair.

RETRO-PHARYNGEAL ABSCESS, FOLLOWING DIPHThERIA AND SCARLET FEVER.

Dr. LEWIS SMITH exhibited a specimen consisting of the larynx, trachea, and one lung attached, removed from a child four years old. About the middle of February the little patient was attacked with scarlet fever, which soon became complicated with diphtheria. It recovered from the fever as well as the diphtheria; at least no deposit was left in the throat. From the time recovery commenced, however, the laryngeal obstruction appeared to increase. Dr. S. saw it after it had been sick for about two weeks with the latter symptoms and about one week before its death. From the long continuance of the affection, the absence of diphtheritic deposit, and from the fact that diphtheria had already existed, the diagnosis of retro-pharyngeal abscess was made. In consequence of the previous energetic treatment which this patient had received for the diphtheria, it was impossible to make any satisfactory examination of the fauces, the resistance to any such attempt being violent and persistent. The examination of the throat was accordingly deferred, a general tonic course being the only treatment adopted. The child died a few days after.

Autopsy.—The trachea and larynx were raised from their bed by an incision from behind, and in the act about a drachm of pus was discovered nearly opposite the epiglottis, which apparently marked the seat of an abscess. The larynx presented rather a jagged appearance, and was the seat of a slight diphtheritic deposit, not sufficient, however, to cause any considerable obstruction to respiration. The trachea presented nearly a normal appearance.

There was in this case also a double pneumonia which had been overlooked during life in consequence of the very marked symptoms which referred all the dyspnoea to trouble in the throat. The pneumonia was confined to each of the lower lobes of the lungs

and also extended to the middle lobe of the right side.

MEASLES AND WHOOPING COUGH FOLLOWED BY ACUTE MILIARY TUBERCULOSIS.

Dr. SMITH also exhibited specimens removed from a female child, five years old, whose sickness commenced with an attack of measles on Christmas. The patient made a pretty good recovery, when it was attacked with whooping cough, the paroxysms of which became very severe. From this time the condition became critical, and there was a marked failure in strength. Dr. Smith saw the child a week before its death, when he noticed dulness under the right scapula. About three days before death the symptoms changed somewhat, and the pulse having fallen from 120 to 80, the brain was suspected to be involved. The suspicion was confirmed by an examination of the pupils. A diagnosis of tubercular meningitis following tubercular pneumonia was then made. The cerebral symptoms gradually progressed, the child grew more and more stupid, and finally died on the eighth of March.

At the autopsy the brain could not be examined. The bronchial glands were found to be enlarged and cheesy. Miliary tubercles, many of them transparent, were scattered throughout the lung. Both lungs were entirely free from pneumonia, except the middle lobe of the left lung, which was hepatized. The spleen was also studded with small tubercles, many of them transparent, some cheesy. There were also seen a few upon the liver, but none upon either the kidneys or intestines.

In conclusion, Dr. Smith remarked that the case was a typical one of its sort, and was of interest in the matter of diagnosis. The child, first attacked with measles, then with pertussis, was much wasted in consequence; the way was thus naturally prepared for tuberculous infiltration, which in its turn was followed by meningitis, the lowering of the pulse and the condition of the pupil giving the usual evidences of the latter condition. In answer to a question from Dr. Knapp, Dr. Smith stated that he believed the pharyngitis to be due to the inflammation of the fauces which preceded it.

INHALATION OF A BEAD—TRACHEOTOMY.

Dr. SAYRE presented a small oblong bead, tapering at each end, which he had removed by tracheotomy from a child aged six years who had been brought to him by Dr. Cleary, of Gloucester, New Jersey. The child had accidentally inhaled the bead five days before, and when seen by Dr. Sayre presented an exceedingly anxious expression of countenance, had a constant irritative cough, and complained a great deal of pain in the chest under the sternum. The respiration was somewhat noisy and the foreign body could be heard like a weaver's shuttle, as it struck against the glottis. Judging from the size of the bead, a companion to which was shown at the time, Dr. Sayre concluded to perform tracheotomy for its extraction. The patient was etherized and the operation done in the usual manner, assisted by his son, Dr. Crosby, and Dr. Yale. The instant the trachea was opened, the bead was coughed out, when the patient took a deep inspiration and was apparently dead. Artificial respiration was kept up for thirteen minutes before the diaphragm would act of its own accord, and then occasionally for half an hour more. A galvanic battery was for most of the time brought in requisition. Finally a piece of inspissated mucus was coughed up, which, having a cavity in its centre corresponding to

the size of the head, was evidently its envelope, or, as Dr. Sayre expressed it, its "overcoat." He supposed that the head, at the moment it was projected from the trachea, lost its "overcoat," which covering at the first inspiration afterwards was drawn into the trachea down to the bifurcation, completely arresting the ingress of air.

Another interesting fact connected with this case was the ease with which the respiration was kept up, and for such a length of time, through the artificial opening.

MORBUS COXARIUS.

DR. SAYRE presented a second specimen, which was the head and neck of the femur removed Jan. 21, 1874, for morbus coxarius, by excision from a girl æt. 10, a patient of Bellevue Hospital. When five years of age, she fell upon her hip and morbus coxarius soon after developed itself. She was treated by plaster apparatus in one of the public institutions, but no extension or counter-extension having been employed, the disease progressed, abscesses soon developed, and in consequence of the attendant exhausting discharges the health became broken down and the patient was reduced to the last degree of emaciation. So deplorable was her condition that the operation was performed more for the sake of allowing her to die easier than for any hope it might give for recovery.

The usual curved incision was made, the head and neck of the femur were entirely destroyed, the acetabulum perforated, and the shaft of the femur was covered with an involucre which was quite firmly attached to the upper rim of the acetabulum, making a tolerably complete ankylosis. The diseased portions extending an inch below the trochanter, section was made at that point. She was dressed in the wire-breeches and did well until the fourth or fifth day, when sloughs formed on her sacrum and ankles, necessitating a transfer to the water-bed. Since that time she has been progressing finely.

A third specimen recently was removed from Lucy Brown, a girl aged four and a half years, whose father died of phthisis. The patient was perfectly healthy until twenty months of age, when she fell down three steps, soon after which accident she developed hip-joint disease. At the end of two years she was brought to the hospital with the limb adducted, flexed, and fixed, with three sinuses leading to dead bone.

An incision down upon the joint found the neck entirely destroyed; the acetabulum perforated in this case also. The femur was sawed off just above the trochanter minor, and the bone being found diseased at that point, the section was made lower down. At the time of reporting the case and at the end of a month after the operation the patient was almost entirely well.

DR. SATTERTHWAITE presented a microscopic slide preparation of the tumor presented at the previous meeting, which specimen, on motion, was referred to the Committee on Microscopy.

DR. KNAPP exhibited a very extensive gummy tumor of the brain, springing from the inner surface of the dura mater. The specimen was removed from a female patient of Charity Hospital, who had been treated during the ten preceding years for syphilitic disease in different parts of her body. She presented the history of that disease through the different phases of primary, secondary, and tertiary. Finally brain symptoms developed themselves, and she eventually died comatose.

The tumor originated in the inner layers of the dura

mater, occupying a round space of about two inches in diameter and projected into the brain-substance with an irregular, nodular surface. In its transverse section it showed a thickness varying from one-eighth to three-fourths of an inch, and two portions differing in appearance and consistence. The centre and the part connected with the dura was hardish and dull yellow, whereas the peripheric portion was somewhat transparent, hyaline, and grayish. It was covered by the arachnoid membrane. The hardened yellow layer consisted of small round cells, embedded in a granular matrix. Cells and matrix were filled with fat granules, in some places so densely that the tissue appeared like an amorphous molecular substance. In the outer, gum-like portion numerous small cells lay in a moderate quantity of homogeneous basis-substance. The majority of the cells were round, had large nuclei surrounded by a thin but conspicuous layer of protoplasm; some of the cells had one or two short offsets, and some were elongated. There was a moderate amount of fat also in this layer and a great many thin-walled blood-vessels. The brain-substance adjacent to the tumor was softened to a great extent.

The nature of the pseudoplasm was unmistakably a syphilitic, gummy tumor. The specimen ranks with the largest of its kind. In an ophthalmological point of view, it adds one to a number of instances where tumors on the convexity of the brain, that is remote from the eye, have produced neuro-retinitis and subsequent atrophy of the optic nerve without specific syphilitic features. A detailed description of the case will be given in the second number of the fourth volume of the *Archives of Ophthalmology and Otology*.

DR. SELL related a case of a sudden attack of coma, with stertor and dilated pupil, which he supposed to be due to gummy tumor of the brain, but unfortunately for the diagnosis the patient recovered.

DR. JANEWAY thought that the case might be one of apoplexy, remarking, that the majority of such attacks were due to syphilitic degeneration of the cerebral vessels.

The Society then went into Executive Session.

Stated Meeting, March 25, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

CANCEROUS BREAST.

DR. BRIDGON presented a cancerous breast removed by operation from a female aged 33, married, and the mother of seven children. The tumor first showed itself two years ago, shortly after which the axillary glands of that side became involved, and six weeks ago the integuments covering the tumor ulcerated. Had it not been for the enlargement of the axillary glands, this case might have been regarded as an ulcerated adenocoele, inasmuch as the areolar tissue covering the growth was perfectly free from infiltration. The operation was decided upon before Dr. Bridgdon saw the case, and although the presence of ulceration and the implication of the axillary glands contraindicated extirpation, the latter was considered advisable in this instance principally from the fact that the skin was not involved. He remarked that he would much sooner remove an ulcerated tumor of this kind than a simple nodular cancer of the skin. In the specimen presented great care was taken to remove the diseased axillary glands.

EXSECTION OF ELBOW.

DR. BRIDGON exhibited a patient, a lad, upon whom he had performed the operation of exsection of the el-

bow joint thirteen months ago. The specimen had been presented to the Society at the time of the operation. After the operation the arm was put up in the usual angular splint, and at the expiration of twelve days passive motion was commenced and continued until the boy could make active motions himself. The movements in the joint were surprisingly perfect, flexion, extension, pronation, and supination being made by the patient with perfect ease.

In alluding to the operation in question, he stated his preference for leaving the periosteum intact, as there was a better chance thereby given for the formation of a new joint, not only synovial membrane being produced, but sometimes the cartilage of incrustation. If too much of the joint be removed there was undue mobility; if too little, there was a liability to excrescences which interfered, more or less seriously, with the motion. Success in any event depended, in a great measure, upon the early resort to passive motion; that is, before the end of the second week after the operation. The shortening in this case was two inches.

SWALLOWING OF A SHAWL-PIN—PASSAGE PER ANUM.

DR. S. CARO exhibited a shawl-pin (two inches long, with a globular glass head) which had been accidentally swallowed by a child twenty months old. Immediately after the accident the first physician at hand, who happened to be a homeopath, was called in, and he at once administered a large dose of castor oil. Dr. Caro, who was the regular family attendant, was then sent for and came armed with the cesophageal bristle-parachute. On examination of the throat nothing could be seen of the pin, and on introducing the instrument for the sake of exploration, the head of the pin was touched high up in the cesophagus and then slipped down into the stomach. Under the circumstances, considering it highly important that the peristaltic action of the intestines should be controlled, three drops of tinct. opii were administered every three or four hours until the desired result was obtained. As much solid food was given as the child would take. Two days after the accident the bowels moved, when the pin was passed, head downwards, without the least trouble.

DR. J. C. PETERS referred to a similar case which had occurred to him in which a shawl-pin of the same dimensions was passed in four days. In the meantime the patient was fed principally on mush.

DR. BRIDGON remarked that he once removed from the neighborhood of the hip-joint a needle which had been swallowed seven years before. He also cited the curious circumstance of a child, thirteen months old, who swallowed a shawl-pin, one and a half inches long, the face or ornament of which was a miniature velocipede and rider. The patient was sent to him by Dr. Aigner. On examining the fauces the foreign body was felt firmly impacted across the glottis. A forceps was introduced and one wheel of the velocipede came away, and it was only after a great deal of difficulty that the entire foreign body was extracted. Notwithstanding the position of the obstruction, there was no difficulty in breathing.

DR. KNAPP believed that so long as a pin had a head there would be no difficulty in its passing through the intestinal canal. The weight of the head was generally sufficient to determine its direction in the long axis of the gut, and if this were not the case and the pin actually penetrated the side of the canal, the head would prevent its going further and the peristaltic action would eventually get the foreign body in the best relative position for passage, viz. with the head downwards.

CENTRAL NECROSIS CAUSED BY EXPOSURE TO COLD.

DR. BLAKE presented a specimen of central necrosis of the humerus removed from a dissecting-room subject for the purpose of calling attention to that peculiar eroded condition of the sequestrum, supposed by some pathologists to be due to syphilis. In the case referred to, the patient presented marked evidence of syphilis in other parts of his body, but whether this condition and the eroded sequestrum had any more than a coincidental relation to each other he was unable to say. In fact, his experience had taught him that the majority of cases of central necrosis was due to cold suddenly applied to a limb while in a profuse state of perspiration—for instance, the sudden and prolonged immersion of a perspiring limb in very cold water. In this connection he exhibited a photographic representation of the bones of the leg and foot which were completely necrosed, necessitating an amputation just below the knee. In that case, the patient, a boy, being in a profuse perspiration, was compelled to stand in the flume of a mill for a considerable time to arrange some of the machinery, the water being quite cold. Following this exposure was a sharp attack of periostitis and a complete death of the bones in question. He, Dr. B., also related another case in which necrosis of the humerus followed the sudden immersion of the arm in a mill-pond, the result of a fall from an overhanging tree, and referred in detail to the case of a central sequestrum of the tibia, caused by the exposure of a sweating limb to cold and wet off the coast of Newfoundland while reefing a jib in a storm. In conclusion, he stated his belief that although many cases of necrosis might be referred to syphilis and scrofulous diathesis, there were still a vast majority of such cases which by careful investigation could, as in the instances cited by him, be directly charged to traumatic causes.

DR. BRIDGON remarked that such exposures as Dr. Blake referred to would no doubt bring about periostitis in persons of a particular diathesis, but under no other circumstances.

DR. BLAKE did not wish to go to extremes, but referred in this connection to the death by phthisis of one of the lions at the Zoological Garden in London. At the autopsy none of the gentlemen appeared to be willing to refer to confinement in the cage as the cause, but persisted in accounting for the disease by assuming that the grandmother of the beast had died of the same disease in South Africa.

(Was there any possibility of proving, however, that the grandmother was not confined at some time in South Africa?)

DR. BRIDGON referred to the fact, in proof of his assertion, that the same traumatic causes would not produce the same effects on different individuals, else almost every other person one would meet would have necrosis.

DR. KNAPP asked if there had been any explanation offered for the occurrence of central necrosis, and being answered in the negative, suggested the cause to be a thrombus of the blood-vessels of the bone due to the arrest of the circulation in the vessels of the skin.

DR. CARO remarked that all through Italy the washerwomen carry their clothes a long distance in baskets on their heads, and while in a perspiration plunge into ponds and remain there often up to their knees in water for the greater part of the day, and also referred to the fishermen in that country who stand in the water all hours of the day and night, and in neither of these cases had he learned that necrosis was at all a frequent disease.

DR. BRIDGON stated that he had often known sailors to be exposed for hours together, and while in a perspiration, to the inclemencies of winter weather, and only partially dressed, with limbs soaked in the coldest of water, and yet he did not recollect to have seen a single case of necrosis as the result.

DR. BLAKE submitted that these were hardly parallel cases. A person who had been subject to violent exertion necessitated the production of some fatigue and relaxation of the tissues; it was while in this condition that a sudden impression of cold brought about the attack.

DR. BRIDGON did not doubt the fact that cold could bring on an attack, but he nevertheless believed there was something behind in the shape of predisposition.

New Instruments.

HEYWOOD SMITH'S SCISSORS.

A SELF-RETAINING CATHETER.

WE have a communication from Messrs. Otto & Reynders with reference to the Heywood-Smith scissors, a description of which we gave in our issue of January 15. These gentlemen say that Mr. Reynders brought these scissors from London on his return from a business trip to Europe, in the summer of 1872, having previously seen them in Brussels. The first ones imported by them were received in May, 1873—were made by Krohne & Seemann, of London, and consisted of a pair without the apparatus for fixing the joints (as figured in THE RECORD of January 15), and another, the illustration of which we append, in which, as will be seen, a ratchet and screw is so arranged as to render the union of the scissors with the long handles immovable, excepting when the screw is turned. To accomplish this a little key is provided. An illustration of this second variety also appears in the catalogue of Windler, the well-known German instrument-maker.

Messrs. Otto & Reynders have shown us an ingenious modification of Holt's "self-retaining catheter." The original instrument, as most of our readers are aware, was kept in place by the two soft rubber wings which projected

from the sides of the catheter, near its tip, as represented in the upper one of the two cuts subjoined. While sufficiently rigid to prevent the instrument slipping from the bladder, they do not present any considerable obstacle to its introduction or removal. The modification, which is shown by the second figure, consists in the division of the barrel of a soft catheter at a distance of about half an inch from its tip, into four equal portions, by longitudinal incisions of about half an inch in extent; two of these portions, on opposite

sides, are then stretched by some means, so that they are permanently longer than the other two, and project as seen in the figure. In introducing or removing the instrument it is only necessary to put the shorter ones on the stretch by introducing a sound through the lumen of the tube until it presses against the tip. By drawing on the catheter all of the divisions will then be made to lie flat along the sound, and the instrument can be entered or withdrawn with the facility of an ordinary catheter.

A NEW NASAL SPECTULUM.

We give also an illustration (half the real size) of a speculum, invented by a German physician named Henschel, which is intended to dilate the nares in operations upon, or examinations of, the nasal pas-

sages. It may be used for one or both nares, and is well adapted, likewise, for examination of the female urethra.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 19, 1874, to April 4, 1874.

PETERS, D. C., Surgeon.—Assigned to duty at Nashville, Tenn., S. O. 43, Dept. of the South, March 21, 1874; and by S. O. 8, Division of the South, March 31, 1874, granted leave of absence for 60 days, on surgeon's certificate of disability, with permission to leave limits of the Division.

WEBSTER, WARREN, Surgeon.—Assigned to duty at Alcatraz Island, Cal. S. O. 29, Dept. of California, March 16, 1874.

HEIZMANN, C. L., Asst. Surgeon.—Relieved from duty with Sioux Expedition, and to resume his duties as Post Surgeon at Fort McPherson, Neb. S. O. 42, Dept. of the Platte, March 23, 1874.

HALL, J. D., Asst. Surgeon.—Granted leave of absence for 30 days—to take effect when a relieving medical officer shall have reported at Fort Benton. S. O. 56, c.s., Dept. of Dakota.

Medical Items and News.

AMERICAN MEDICAL ASSOCIATION.—The Twenty-fifth Annual Session will be held in the city of Detroit, Mich., on Tuesday, June 2d, 1874, at 11 A.M.

"The Chairmen of the several sections shall prepare and read, in the general sessions of the Association, papers on the advances and discoveries of the past year in the branches of science included in their respective sections. . . ."—By-Laws, Art. II., Sect. 4.

Sections.—*Practice of Medicine, Materia Medica, and Physiology*: Dr. N. S. Davis, Chicago, Illinois, Chairman. Dr. Geo. E. Frothingham, Ann Arbor, Mich., Secretary.

Obstetrics and Diseases of Women and Children: Dr. Theophilus Parvin, Indianapolis, Ind., Chairman. Dr. Montrose A. Pallen, St. Louis, Mo., Secretary.

Surgery and Anatomy: Dr. Samuel D. Gross, Philadelphia, Pa., Chairman. Dr. Alonzo Garcelon, Lewis-ton, Me., Secretary.

Medical Jurisprudence, Chemistry, and Psychology: Dr. A. N. Talley, Columbia, S. C., Chairman. Dr. E. Lloyd Howard, Baltimore, Md., Secretary.

State Medicine and Public Hygiene: Dr. A. Nelson B.-H. Brooklyn, N. Y., Chairman. Dr. A. B. Stuart, Winona, Minn., Secretary.

"Papers appropriate to the several sections, in order to secure consideration and action, must be sent to the Secretary of the appropriate section at least one month before the meeting which is to act upon them. It shall be the duty of the Secretary to whom such papers are sent, to examine them with care, and, with the advice of the Chairman of his section, to determine the time and order of their presentation, and give due notice of the same. . . ."—By-Laws, Art. II., Sect. 5.

The following Committees are expected to report: On Cultivation of the Cinchona Tree: Dr. L. J. Deal, Pennsylvania, Chairman. On the Treatment of Fractures: Dr. Lewis A. Sayre, New York, Chairman. On Gynecology: Dr. M. A. Pallen, Missouri, Chairman. On some Diseases Peculiar to Colorado: Dr. John Elsner, Colorado, Chairman. On Rank of Medical Corps of the Army: Dr. J. M. Keller, Kentucky, Chairman. On Prize Essays: Dr. G. K. Johnson, Michigan, Chairman. On the Progress of Otology: Dr. D. B. St. John Roosa, New York, Chairman. On American as compared with Foreign Winter Cures: Dr. H. R. Storer, Massachusetts, Chairman. On Railroad Injuries: Dr. W. F. Peck, Iowa, Chairman. On the Therapeutics of Ammonia: Dr. P. J. Farnsworth, Iowa, Chairman. On the Relation of Physiology to the Practice of Medicine: Dr. E. W. Gray, Illinois, Chairman. On Puerperal Fever: Dr. W. G. O. Smith, Kentucky, Chairman. On the Legal Relations of Moral Insanity: Dr. E. Lloyd Howard, Maryland, Chairman.

The following amendments to the Plan of Organization are to be acted upon:

By Dr. N. S. Davis, Illinois:

Strike out the second paragraph of Art. II. and insert the following:

"The delegates shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies as are recognized by representation in their respective State

Societies, and from the Medical Department of the Army and Navy of the United States."

Also, strike out the fourth paragraph of same Article, and insert:

"Each State, County, and District Medical Society, entitled to representation, shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number."

"The Medical Staffs of the Army and Navy shall be entitled to four delegates each."

By Dr. P. Pineo, of Massachusetts:

Art. II., second paragraph, after "Army and Navy," insert "and the Marine Hospital Service of the United States."

By-Laws, Sect. 6, after "the chiefs of the bureaux of the Army and Navy," insert "and the supervising surgeon of the United States Marine Hospital Service."

By Dr. E. L. Howard, Maryland:

Art. IV., Strike out second clause of first paragraph, and insert:

"They shall be nominated by the Judicial Council, and shall be elected by vote on a general ticket."

By Dr. A. S. Maxwell, of Iowa:

"Resolved, That in view of the many and important duties imposed upon the Nominating Committee, the Medical Society of each State and Territory that elects delegates, be requested, when selecting delegates, to nominate one member of such delegation as their member of the nominating committee, and also designate the mode of filling vacancies."

By Dr. A. M. Pollock, of Pennsylvania:

Art. VI., first paragraph, strike out the word "five" and insert "ten."

By-Laws, Art. 5, first paragraph, strike out "five" and insert "ten."

Secretaries of all medical organizations that have adopted the Code of Ethics are respectfully requested to forward to the undersigned a complete list of their Officers, with their Post-Office addresses, and the number of their members in good standing. This is the only guide for the Committee of Arrangements in determining as to the reception of delegates.

It will also enable the Permanent Secretary to present a correct report of the Medical organizations in fellowship with the Association.

WM. B. ATKINSON, M.D., Permanent Secretary.

BRAITHWAITE'S RETROSPECT.—In the issue of March 2d, in *THE MEDICAL RECORD*, was inadvertently printed, "*Braithwaite's Retrospect* had ceased its existence with the January number." It should have read "*Rankin's Abstract*."

RECEPTION HOSPITALS.—APPOINTMENTS.—The following appointments have been made by the Commissioners of Public Charities and Corrections, upon the recommendation of the Board of Examiners (Drs. Hamilton, Sands, and Loomis).

Park Reception Hospital.—M. B. Earley, M.D., House Surgeon; Wm. B. Hull, M.D., First Assistant; M. L. Wengler, M.D., Second Assistant (*Externe*); T. E. Wilson, M.D., Ambulance Surgeon.

Ninety-ninth Street Reception Hospital.—W. N. Campbell, M. D., House Surgeon; A. H. Gorlet, M.D., Assistant; C. A. Nolan, M.D., Ambulance Surgeon.

All of whom entered upon their duties on the first day of April.

BELLEVUE HOSPITAL.—The question of expediency regarding the reconstruction of Bellevue Hospital on the pavilion plan is again being agitated. Every one interested in hospital management would be glad to see this done.

Medical Department of Life Insurance.

WHAT EFFECT DOES SYPHILIS HAVE UPON THE DURATION OF LIFE?

By FRED. R. STURGIS, M.D.,

ASSIST. SURG. MANHATTAN EYE AND EAR HOSPITAL, N. Y. CITY.

PART II.

Hereditary predispositions.—Any inherited taint, whether tubercular, scrofulous, or otherwise, will undoubtedly be more or less affected by this disease, and will perhaps be accelerated by it, and vice versa. But what I wish especially to dwell upon now, is, what effect congenital syphilis would have upon the duration of life.

The larger proportion of deaths from syphilis occur in subjects under five years of age; indeed, if we may rely upon the published statistics, the average mortality is nearly 85 per cent. for New York City and over 63 per cent. for Philadelphia. This in the former city embraces a period of six years, in the latter of twelve. For the year 1871, in New York City, out of a total of 142 deaths from syphilis, 120 occurred in children under five years of age; in Philadelphia, out of 19 deaths, 12; and in London, out of 352 deaths, 314. Let us see, out of the remaining deaths, how many occurred before the thirtieth year was completed. In New York City, out of a balance of 22 deaths, 12 died before the 31st year.

In Philadelphia, out of a balance of 7 deaths, 2 died before the 31st year.

In London, out of a balance of 38 deaths, 21 died before the 31st year.

It is probable that the cause of the large proportion of deaths between the age of five, and before the completion of the thirtieth year, is indirectly due to the influence which puberty exercises upon the development of the later symptoms of hereditary syphilis, and this view seems to be supported by the opinion of a recent French writer. He says: "Puberty in both sexes, and pregnancy and the menopause in women, like most diseases, play the part of occasional causes. The age of puberty is a time at which cases of late hereditary syphilis hardly ever fail to show themselves. Menstruation, and especially the menopause, act in the same manner as do pregnancy and childbirth, and like those two conditions, tend to favor the appearance of syphilitic lesions."*

I have taken the limit of thirty years, and assumed that the cases which proved fatal within that time were due to hereditary causes, and in this course I think I am justified for the following reasons: 1st, That the time during which syphilis is *acquired* is generally between the ages of twenty and thirty, a period when the disease is less likely to prove fatal, from the patient being better able to withstand the debilitating effects; and 2d, Because the disease seldom kills so rapidly as in ten years, and then only in exceptional cases. What the cause of death was in those who died under five years, will, I scarcely think, be questioned; it is not likely to have been from acquired disease, unless these infants were strangely precocious in their tastes and habits.

Out of those who died between 5 and 30 years of age, 4 died in New York between the ages of 5 and 20, and 8 between 20 and 30. The first set (4) we may at once dispose of. It is very unlikely that death would have been caused from syphilis acquired be-

tween the ages of 5 and 20. Of the remaining 8, between 20 and 30, although it is not so clear, it is still sufficiently improbable to cause doubt; so that we then have 10 deaths left which we can fairly ascribe to acquired syphilis. Of these, 6 died between 30 and 40, 2 between 40 and 50, and 2 between 50 and 60.

The Philadelphia record stands thus: Out of those who died between 5 and 30 years of age, 2 died between 20 and 30, leaving 5 deaths from acquired syphilis; of these, 2 died between 30 and 40, 2 between 50 and 60, and 1 between 60 and 70.

The London record is as follows: Out of those who died between 5 and 30 years of age, 6 died between 5 and 20, and 15 between 20 and 30, leaving 17 deaths from acquired syphilis; of these 5 died between 30 and 35, 7 between 35 and 45, and 5 between 45 and 55.

To sum up, therefore, we may say that hereditary syphilis does, up to the age of 20 at least, shorten the expectation of life, and probably up to that of 30.

Thus far, my dear Doctor, I have, as carefully and correctly as the means at my disposal allowed, tried to answer the questions you have put me, and am almost disheartened when I look back and see how evasive and vague the replies have been; but should this article elicit more carefully compiled statistics and more direct and accurate knowledge of the effects syphilis has upon the duration of life, I shall feel compensated for my time and trouble.

This brings us to the third division of your list of questions, which reads:

"In what way does syphilis shorten life?"

(a) "Does it do so through the development of some of its own peculiar lesions, and if so, to what extent?"

(b) "Does it render a person more liable to other diseases, as, for instance, the inflammations—meningitis, pneumonitis, pleuritis, and carditis?"

(c) "Does it favor those diseases which are due to a degeneration of the walls of the blood-vessels—apoplexy, aneurism, valvular disease of the heart?"

(d) "Does it favor the development of those changes in the brain or spinal cord whose manifestations go by the name of 'insanity,' 'epilepsy,' 'anaesthesia,' etc.?"

There is no tissue of the human body which is not liable, in the course of the disease, to become attacked; so that in the advanced stages of syphilis any one of the forms which you have mentioned may and do occur; thus we find a syphilitic meningitis and a syphilitic pleuritis, a specific neuritis as well as specific mania, epilepsy and arteritis—in short, each non-specific ailment has its specific counterpart. To answer your question as to how these cause death, let me discuss the pathology of syphilis. In a few words, it is this—infiltration, exudation, and molecular destruction. These destructive changes, which go on more rapidly and fatally the older the date of the disease, are usually accompanied by changes of assimilation and nutrition. Bearing in mind what an exhausting disease syphilis is, even from its inception, and what changes it induces in the blood-cells themselves (witness Ricord's and Grassi's researches in that direction), we can the better understand how it may fatally undermine the general health, and produce death by exhaustion. You will remember, in recording the causes of deaths from syphilis in the London hospitals, what a prominent part this same exhaustion played—indeed, we might call it an exhaustive poisoning. These later stages, the so-called tertiary and quaternary, are especially marked by deep and chronic destruction, which makes them especially dangerous, and, when associated with changes in assimilation, well-nigh hopeless.

We may, therefore, sum up the evidence as follows:

* Lancereaux, op. cit.

1. Syphilis destroys life from exhaustion, and non-assimilation, due to a poisoning.

2. To a certain extent it does render a person more liable to other diseases, as, for instance, the inflammations; but it does so in this way, by the deposition and breaking down of its own peculiar products in the tissue of the organ attacked, and only indirectly by destruction of the tissue proper of the part.

3. In the same way it favors the development of those changes in the brain or spinal cord whose manifestations go by the names "insanity," "epilepsy," etc.

Now, although all syphilitics are liable to be attacked by the later stages, fortunately they, practically, do not go so far; and my own experience leads me to believe that only a small proportion of those who contract the disease suffer afterwards from the tertiary manifestations. This would also seem to be the opinion of M. Landrieux, of Paris, who, in an interesting memoir on "Les Pneumopathies Syphilitiques," says: "Suivant toutes vraisemblances, c'est une manifestation rare de la syphilis, ainsi du reste que toutes espèces d'accidents tertiaires, ce qu'on doit mettre sur le compte des traitements bien dirigés, et sur ce que, chez beaucoup d'individus, le virus s'épuise, disparaît de l'organisme."

Your next two questions, my dear Doctor, I shall take the liberty of condensing into one, as they require pretty much the same answer, and that one I shall put into the shape of a few rules, to guide the medical examiner in determining when to, and when not, recommend a syphilitic risk for life insurance.

1. It is, as a rule, better not to insure any patient in whom the disease is still present, no matter how light the symptoms may be, for you cannot predict accurately what may occur.

2. This, however, does not argue that the same man may not, after he has recovered from his disease, be a good risk. You see, Doctor, I believe syphilis to be a curable disease. The average time allowed for recovery is two years; of course some will need more, some less. Then allow two more years from his last symptoms before becoming a candidate for life insurance; in other words, four years from the date of his disease. This will answer for the majority of cases where the disease has been of medium severity; where the patient's history points to an advanced stage, let three years have elapsed from his last symptoms until his examination.

3. Be especially careful to ask the date of the last symptoms and their character, for the older the date, and the lighter and more superficial the symptoms, the less risk on the life insurance.

4. Persons with a family history of tuberculosis, cancer, and such hereditary diseases, are, at the best, I believe, considered shy cases. They are doubly so when they have had syphilis of an advanced type, e.g., nervous, visceral, or ulcerating syphilis. If their disease have been mild, with the two years' period of recovery above mentioned, the syphilis need not stand as a bar to their insurance.

5. Not so, however, those who are the subjects of hereditary syphilis. They are rotten "ab ovo usque ad mala," and if not actually presenting the symptoms of their congenital disease, their vitality is impaired, their nutrition often imperfect, and they are prone to succumb to almost any extra strain which may be imposed upon them. Better have nothing to do with them. And—

6. Inasmuch as patients are proverbially prone to deceive the examiner under such circumstances, not from wilfulness only, but from ignorance also, obtain,

so far as you can, a certificate from the physician under whose care they were for the disease.

16 WEST 32d STREET, NEW YORK.

THE MEDICO-LEGAL ASPECTS OF LIFE INSURANCE.*

By EDWARD HENRY SIEVEKING, M.D.,

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS; PHYSICIAN TO ST. MARY'S AND THE LOCK HOSPITALS; PHYSICIAN EXTRAORDINARY TO THE QUEEN, ETC.

A FEW points, and among them some that especially bear upon the medico-legal aspects of life insurance, and which have not found a place in the previous chapters, remain to be considered.

It is not customary among respectable offices to underbid one another; therefore previous rejection at another insurance company militates strongly against the acceptance of a life. At the same time it would be cruel not to take a life into consideration that proposes in proper form, and it necessarily happens not only that different views may prevail as to the importance of certain indications, but also that circumstances may have occurred since the rejection which might justify a favorable interpretation of adverse features. In many morbid conditions time effects material improvements, and residuary affections which once threatened danger may have disappeared altogether, or have assumed so quiescent a form as to present no unfavorable symptoms. Thus, a person recently recovered from a pleuritic seizure might be deemed ineligible within six weeks of his illness, but after a year or more, the health might and probably would be so perfectly restored as to remove all objections, unless some past indications of morbid action had arisen. Another suffering from a paralytic affection, consequent upon diphtheria, would be unacceptable while there was any trace of paralysis, but admissible when all nerve symptoms had been removed. Instances of this kind might be indefinitely multiplied.

On the other hand, previous acceptance by any office does not supersede the necessity of a strict scrutiny, when the same individual again proposes to insure. The lapse of a few years very frequently reveals new features which give the case a totally different aspect. Parents, or other relations previously in good health, may have died, and their fatal illnesses may show a taint which was not before manifest. The applicant may himself have suffered from illnesses exhibiting an hereditary predisposition that would diminish his expectation, or he may have become the subject of morbid influences affecting vital organs of a different character, equally impairing his prospect of longevity. It is so much the custom of English offices to interchange their experiences with regard to their policyholders, that a certain solidarity exists between them, and a comparison of papers and the contained statements not unfrequently exhibits discrepancies, which afford considerable assistance in estimating the value of a life. Thus, a short time since, a life was proposed to an office and reported upon by an examiner of eminence. The proposer stated that he had suffered from an attack of rheumatism. A reference to the medical attendant proved this to have been a severe attack of rheumatic fever, for which seven years extra were charged, but the proposer not agreeing to these terms, the proposal was not completed. Another

* Reprinted from the author's recent work, entitled "The Medical Adviser in Life Assurance." London: J. & A. Churchill, New Burlington Street, 1874.

Orders may be sent to Wm. Wood & Co., 27 Great Jones street.

equally careful office having taken the life at the tabular rates, a comparison of the papers of the two companies showed that the proposer, having ascertained the weak point in his case, had stated in his replies to the second office that his rheumatic fever was "slight rheumatism," and that he had required no medical attendant. Applicants even unintentionally are apt to exhibit considerable obliviousness of matters connected with their own health or that of their relations; it is therefore useful to be able to remind them of statements made on a former occasion, and to compare accounts given at different periods. Wherever there is a suspicion that there has been any attempt to deceive and make a fraudulent or a highly colored statement, the application had better be refused altogether, as one such intentional error would necessarily more or less invalidate all other averments, and in case of future disputes, make the company a particeps criminis, if it could be shown to have connived at the fraud by knowingly accepting a life offered under false pretences.

The physician has an important interest in the medico-legal aspect of life assurance, and to estimate that fully, it may be worth while to refer briefly to what the life-assurance contract realizes, and in what terms the contracting parties enter into it. In all ordinary cases a person, either of his own accord or at the suggestion of others, comes to an insurance company and offers to pay an annuity or yearly sum during his life, if the company will undertake to pay his representatives a certain sum by way of reversion after his death. This being the chief condition of the contract, it remains to settle the two sums. The one, the proposer determines himself by naming the amount for which he wishes to be assured. The other is fixed by the office on the faith of certain statements made by the proposer, and of a medical examination to which he subjects himself. This examination, however carefully or ably made, must be incomplete without the statements comprising the age, the habits, and the personal and family history of the applicant. If these statements are not made fairly and truly, one of the contracting parties, *i.e.* the assurance company, is induced to enter into the contract in ignorance of its exact nature. Of the three subjects just mentioned, the age is capable of positive proof, and offices, therefore, take the statement of the age for granted, subject to subsequent evidence of correctness; but particulars as to habits and history can only be obtained on the faith of the proposer. Some persons are under the impression, that the undergoing a medical examination relieves them from the responsibility of giving false information on these points, but this is an error. One of the greatest authorities on the Law of Life Insurance* quotes the opinion of a learned judge on the subject to the following effect: "Not only must the party proposing the insurance abstain from making any deceptive representation, but he must observe the utmost degree of good faith, *uberrima fides*. Not only is he required to state all matters within his knowledge which he believes to be material to the question of insurance, but all which in point of fact are so. If he conceals anything which he knows to be material, it is a fraud; but besides that, if he conceals anything which may influence the rate of premium, which the underwriter may require, although he does not know that it would have that effect, such concealment entirely vitiates the policy. An entire disclosure must then be made of all material facts known to the assured; and not only so, but all

representations made by him as to material facts must be substantially correct; and to this may be added, that where a representation amounts to a warranty, it must not only be substantially, but literally true."

For convenience, the assurance offices have adopted a form called a declaration, on which the requisite information should be given. This form is usually annexed to the form of the medical report; and although some offices incorporate it with the report, and leave it to the medical examiner to put the questions and write down the answers as they are given by the applicant, the majority of the offices—while they annex one form to the other, thus recognizing the necessity that the medical adviser should have the applicant's replies before him in order to enable him to fill up the other properly—make the declaration a distinct document, which has to be signed by the proposer. The declaration generally has the following words, or something to the same effect, at the foot: "I declare the above statements to be true, and admit them as the basis of my contract with the — Company." The questions in this declaration are generally read over to the applicant by the physician, and the former appends his signature to the answers after they are taken down.

The modern custom appears to be to put a distinct question as to each important disease of ordinary occurrence, and the questions doubtless appear to the inexperienced to be unnecessarily numerous. But this is quite as much in the interest of the proposer as of the office, and to prevent the former from forgetting any fact that ought to be mentioned. At the same time the responsibility of giving full information rests with the proposer, as laid down in the quotation previously given from Mr. Bunyon's work. He subsequently* adds the following authoritative statement: "If the proposer leads the insurers into error by inducing them to compute their risk upon circumstances not founded in fact, so that the risk actually run is different from that intended to be run, the contract is as much at an end as if there had been a wilful and false allegation, or an undue concealment of circumstances."

This being the law, it appears to be the duty of the medical examiner to protect both the proposer and the office from the results of its being broken. In practice, offices rarely dispute the payment of a policy, unless fraud of a most glaring and deliberate kind has been committed; but it cannot be doubted that frauds are practised upon them, and that by the withholding or misstatement of certain facts, directors are frequently led to pass lives at the ordinary rate, when they ought to have been charged an extra premium. Take a case like the one previously alluded to, where a proposer had been affected with rheumatic fever, and who states he had only had a slight attack of rheumatism. The former, assuming the proposer's age to be thirty, would necessitate an extra charge of seven years, while the latter would not render an addition necessary. The fraud here consists in the value of the difference in the premiums, or an assurance for £1,000 (say Carlisle four per cent.) = £78 6s. Or, in the case of a man whose mother died of consumption, but who states that she died after childbirth, there ought to be an addition of ten years; and if, in consequence of his false statement, he is taken at the ordinary rates, the office is defrauded of £125 12s.

Hence, it should be the duty of the medical man to impress upon the proposer the necessity of truth and exactness, and to cross-examine him on any point on which he fails to reply frankly and satisfactorily.

* A Treatise upon the Law of Life Assurance, by C. J. Bunyon, M.A., p. 30. London, 1854.

* *Loco citato*, p. 33.

Some people think it no harm to benefit themselves at the expense of a public company, but by the prevailing constitution of assurance societies, by which a large majority of the policy-holders are assured on the system of participating in the profits, the injury done affects the members, and each one bears his proportion of it.

Another point in connection with the subject under consideration is the relation of the private medical attendant. One of the questions addressed to a proposer is: Who is your ordinary medical attendant? and many controversies have arisen on the answer given. It is clear there is room for serious frauds here, as experience has shown. It is the custom in one London office always to constitute the private medical attendant its own examiner *pro tempore*, and to give an additional fee in consequence. The definition of what constitutes a private medical attendant is given in the papers of the office in question, thus: The medical man who has most frequently attended the life proposed.

Life assurance now being widely diffused over the country, this plan would be practically adopted by many offices, for in small towns and villages it must often happen that the medical examiner is also the medical attendant of the proposer. But in populous towns and districts this is less likely to happen, and we are then driven back to the question. The reply would necessarily yield the name of the practitioner who could give the most complete information regarding the proposer. It might happen that a candidate for insurance had been attended by one medical man for a dangerous illness most prejudicial to longevity, and soon after by another for some trifling ailment. To name the latter as the ordinary medical attendant might be a compliance with the query in its literal sense, but certainly not with its spirit. In the case of *Everett versus Desborough*,* it was laid down that a reference to a person who immediately before the time at which the policy is effected has been casually consulted for trifling maladies, will not satisfy the requisition for a reference to the usual medical attendant, although the person who had formerly attended may have retired from practice at the time.

We cannot put the matter in a clearer and more succinct form than by laying before our readers the following further extract from Mr. Bunyon's work, which seems to comprise all the legal bearings of the subject:

"The meaning of the question 'Who is your usual medical attendant?' was elaborately considered in the case lastly referred to (*Everett v. Desborough*). 'What is the grammatical sense of that question?' observed the Court: 'It is in the present tense.' Suppose a person goes to effect a policy on his life, who had no medical attendant in the last year; if the answer to the question were, 'I have no such medical attendant,' must not that question of necessity be followed by another, which is, 'Who was your former medical attendant?' The terms and nature of the question prove that it was designed to extract from the person *who is the medical attendant best able to give an account of her constitution at the time*; and if she has no usual medical attendant in the precise grammatical sense of the question, it appears to me that she is bound to mention who is the medical attendant who could give that information. The facts of the case appear to be, that this lady had been attended by Mr. Duck, her medical man at Bristol, for a considerable time during several years, and down to the time of her marriage in

December, 1832. Previously to her marriage she had made one or two attempts to effect a policy on her life, and Mr. Duck had been referred to as her medical attendant, and on his representations the parties with whom it was proposed to effect the insurance had declined the risk. She was married in December, 1832, and it was stated that from that time Mr. Duck ceased to attend her, but that a gentleman of the name of Day, who had been attending her husband and was the usual medical attendant of the family, upon one or two occasions, not being called in to attend her expressly, but incidentally calling, had given her some slight advice of such little note that he had made no memorandum of it in his book. When called upon to answer the question, she replied, 'Mr. Day,' who being examined by the company's agent, said she was perfectly well for aught he knew, and that he had never attended her professionally at all; and on trial, that he had attended her once or twice; he was not sure that he had attended her a second time, but he had once or twice given advice to her. The question was left to the jury to say whether Mr. Duck or Mr. Day was her usual medical attendant; but it appears to the Court that there was another question behind, namely, whether, from the peculiar circumstances under which Mr. Day was introduced to her notice, he could be called her usual medical attendant at all. It appears to us that it should have been laid down to the jury, that, if she was aware that the person whose name she gave could not be the proper person to render the account that the defendant wished to have of her, it was her duty to have mentioned the circumstance, and to have stated that although Mr. Day was a person to whom they might refer, he was not the usual medical attendant, but that the usual attendant had been Mr. Duck. To illustrate this, suppose Mr. Day had never attended her at all, but that when she married she ceased to have any medical attendant; suppose she had answered, 'I have no usual medical attendant,' that answer would have been followed by the question, 'But had you ever any usual medical attendant?' She must have known that the question was intended to elicit from her an answer designating the person who could give the best information respecting the state of her constitution."

It is well known that for a long time a controversy was carried on between the life offices and the medical profession on the subject of medical fees. It was urged by the former that a proposer for an assurance was bound, as a person selling a property, to prove his title at his own cost, but that the company had the right to make all needful requisitions. On the other hand, it was argued that if so, the medical man, being in the pay and interest of the proposer, was rather his advocate. This contest has now ended. The offices admit that the medical man, if asked to report, does so in their interest, and should be paid by them. It has been suggested that the sympathies of the private medical attendant are on the side of his patient; but practically, if this is the case, it is not found to warp his judgment and to induce the return of false statements. If he allowed his feelings or prejudices to guide him, it is the more necessary that he should be acquainted with the clear injunctions of the law as to his duties, which are calculated to induce him to be perfectly frank, and to make a full statement of everything within his knowledge that is at all likely to affect what is termed the basis of the contract of life assurance. Anything like reservation clearly jeopardizes the entire transaction, and places the policyholder at the mercy of the company.

The medical officer of an insurance company has an

* Bunyon, *loc. cit.*, p. 44.

important office to fulfil in examining the claim papers; he has to satisfy himself of the nature of the evidence of death, and he ought especially to inquire into the causes of the fatal issue. In doing this he would have three objects in view: first, to ascertain that the death is attributable to natural causes; second, to determine whether there is any discrepancy between the statements of the late policy-holder, regarding his health and the fatal disease; and third, to extract from each individual case any information that may avail him in judging of future lives to be submitted to his judgment.

A death from natural causes excludes the idea of suicide, which almost universally invalidates a policy; though for our part we are strongly of opinion that, unless suicide is committed within a certain space of time from the date of the first issue of the policy, it ought to be regarded like any other accident, to be provided for by the rates of insurance.

The number of suicides in England in 1871 was 1,495, of which 1,103 were males, and 392 females; the average for London alone from 1846-1850 was about 240 annually, of which less than half were females. The proportions manifestly vary somewhat in town and country; the total number for London in 1871 was 207; therefore, considering the vast increase of the population during the last twenty-five years, this looks like improvement. Suicides occur chiefly in the middle and upper ranks of society, whose position and property fluctuate much more, involving greater anxiety and mental distress than is the case among working classes; hence, although the proportion to the entire population is small, the proportion falling upon insurance companies, which are chiefly resorted to by the former, is comparatively large. This is further corroborated by the table quoted from Mr. Smce, Junior, at page 117, where the deaths from violence, which include suicides, are found to constitute a high ratio, though this of course is imperfect evidence, as we have not the numbers of deaths from other causes included under the head of violence. Judging by the evidence at our disposal, it appears that five claims in 1,000 are due to suicide. Suicide is a direct result of what is termed civilization. The proportion which it bears to the population exhibits a close ratio to the advance of education and wealth. It is generally larger in towns than in the country. Casper,* the great German medico-legal authority, gives the following table as the result of his inquiries into the frequency of suicides in certain towns of importance:

	No. of suicides to 100,000 inhabitants.	One suicide to number of inhabitants.
Copenhagen	100	1,000
Paris	49	2,040
Hamburg	45	2,222
Berlin	34	2,941
London	20	5,000
Elberfeld	20	5,000

Quetelet also gives the authority of his imprimatur to the following quotation from Balbi,† which the reader may like to refer to as bearing upon the general social aspect of suicide. The data appear to have been collected in or about 1827.

The number of suicides were, in
Russia, in the proportion of one to 49,182 inhabitants.
Austrian Empire, " " " 20,900
France, " " " 20,740 "

Philadelphia, proportion of one to 15,875 inhabitants.				
Prussia, " " " 14,404 "				
Baltimore, " " " 13,656 "				
Boston, " " " 12,500 "				
New York, " " " 7,797 "				

To the list of the sad sequelæ to intemperance we have also to add suicide, with which it is too often found associated. Dr. Farr has shown that the professions peculiarly addicted to drunkenness have more than their due proportion of suicides. "Drunkenness," he says, "leads to this, but drunkenness is a sort of indirect suicide, and both are tendencies of the mind indulged often from the same motives, and promoted by similar causes; for in drunkenness the wretched find not only the gratification of an appetite, but the suspension of natural consciousness—in death they seek its cessation." To pass from these general statistics to the consideration of the subject immediately before us, it may be stated that it is not always easy to determine whether an individual has died by his own voluntary act or not; and as insurance companies shrink from contesting their liability, although under their contract fully empowered to do so under certain conditions, owing to the odium which they incur, unless they are certain of being able to prove the correctness of their suspicions, it is tolerably certain that a considerable number of claims have been paid, although life had been terminated by suicide. A claim of this kind lately came before us, where morally there could scarcely be any doubt that a captain, who, without adequate motive, not only refused to leave his sinking ship after his mate and all the sailors had taken to their boats, but even lay down in his berth, and declined urgent solicitations to escape from certain death, was guilty of suicide; yet the company consented to pay the policy, owing to the conviction that a jury would certainly have looked upon him as a martyr and a hero. Most persons of any experience in these matters will probably recall more marked illustrations of this feature in life insurance.

However, we repeat that we would not even allow well-proven suicide to invalidate a policy after a lapse of say five years, because it is not to be supposed that any one would take out a policy with the view of defrauding the company so long beforehand, because it is generally desirable to fix a time at which all policies become absolutely indisputable, and because there is sufficient evidence to justify the belief that suicide is generally the consequence of a morbid condition of the body or the mind, or both. If all insurance companies agreed to adopt some principle of the kind, and resolutely acted upon it, the temptation to this species of fraud would be removed, and the poor survivors would not lose what in these cases is often their only stay.

A certain amount of sympathy cannot be denied to persons who, with the intention of benefiting those dear to them, make away with themselves. The moral obliquity which is associated with suicide is often to be interpreted as a perversion of one of our best feelings; and the individual who commits the act doubtless thinks at times that he is committing an act of self-sacrifice for the good of others. The anxiety and distress which commonly lead to self-destruction are generally an efficient cause in overthrowing the balance of the mind, and if we cannot agree with the almost universal verdict of juries, that "temporary insanity" palliated the deed; neither can we doubt that before a higher tribunal an intimate knowledge of the physical and moral circumstances surrounding the case would, in many cases, conduce to a verdict that it belonged rather to the category of disease than of crime.

* Quoted by Quetelet, *Sur l'Homme*, vol. ii, p. 147. See also two valuable papers on suicide, by Mr. Jopling, in the *Assurance Magazine*, vols. i. and ii.

† "La Monarchie Française comparée aux principaux états du globe."

But if a sentiment of pity softens the asperity of our feelings with regard to the individual who defrauds the insurance company by taking away his own life, no expression of condemnation can be too strong to apply to those who, for the sake of this species of gain, contemplate and carry out the destruction of others. Unfortunately, our records exhibit many instances of this form of crime; wives, parents, brothers, friends, have been insured and murdered for the sake of the proceeds of the policy. In the lower ranks of life, burial clubs have been repeatedly shown to act as incentives to crime of the same kind. All through society, therefore, it behoves the medical man to be on his guard, that he may detect any indication of a life having been tampered with. In this respect he cannot refuse to watch over public morality; and in connection with life insurance, he has the further motive, if any be required, that other important interests are committed to his charge, and that the discovery of this form of crime rests especially with him.

In conclusion, we would express a hope that we have conveyed to our medical readers, throughout, the high moral responsibilities which they incur in undertaking the work which legitimately pertains to them in connection with life insurance. Although we have had occasion to advert to the possibility of shortcomings in members of the medical profession, our general experience, now of many years' duration, of the work done by them, justifies the assertion, that as a rule they act upon the principle enunciated in the passage which Shakspeare puts into the mouth of one of his chief characters:

"'Tis not my profit that does lead mine honour.
Mine honour, it."

Life insurance involves interests of the greatest importance to the individual and to society; and here, as in many other matters affecting the welfare of humanity, the medical man is one of the chief guardians of social morality and civilization. The more fully he realizes the elevated aims that he should aspire to, the more he aids his fellow-man in his onward progress, and the more he fulfils the great obligations which he takes upon himself in joining the noblest and the most unselfish of all professions.

MEDICAL EXPERTS IN THE SELECTION OF LIVES.

BY A MEDICAL DIRECTOR.

It is probably known only to a few members of the medical profession, that a majority of the prominent life-insurance companies have recently organized themselves into an association bearing the name of the CHAMBER OF LIFE INSURANCE.

The central idea of this association—if we are rightly informed—is to obtain concerted action in all matters which tend to promote life insurance interests in the abstract. Thus, for instance, the chamber is discussing, among other things, the advisability of having but one list of medical examiners. The mere fact that the suggestion of such a project emanates from the executive, and not the professional department of life insurance, indicates a great step in advance toward the establishment of proper relations between the medical profession and the managers of life companies.

The notion, which many life insurance officers still entertain, that it is not quite safe to have an applicant examined by the regularly appointed medical

examiner of a rival company, is utterly wrong, as it implies a degree of corruptness among physicians which the facts have never justified.* The action of the chamber, however, casts aside this imputation, by deciding that hereafter the function of the medical examiner is to be purely that of an expert in the selection of lives, and that in the performance of this duty he can be trusted to treat all companies impartially. If, then, our information be correct as to the coöperative plan which the chamber proposes to introduce, we can only wish it full success in carrying out the necessary steps to accomplish this important radical change, for we believe that it is the only way in which the profession, as a body, can be brought into closer and more responsible relationship with the business of life insurance. To appreciate the benefits to be expected from such a change, we must glance at the present status of things.

Take, for instance, a town of some three or four thousand inhabitants. Here we shall find from six to twelve physicians in more or less active practice. The most prominent among them is probably the medical examiner for three or four of the best life companies, who have taken the pains to find out the relative standing of physicians in that place. But all the other physicians in the place—he they professionally good, bad or indifferent—are also medical examiners for various companies, and probably receive at least a full share of this sort of patronage.

Now what is the practical result, we would ask, of this indiscriminate examination of lives for insurance? Does it not endanger the financial prospects of the company, and does not the distribution of this professional patronage among so many physicians tend to alienate the better men among them, or at least to weaken their interest in and sense of responsibility toward the companies? We certainly believe that the existing wide-spread indifference of physicians to insurance matters, is due in great measure to the lack of constancy manifested by the home offices, in their dealings with the physicians whom they employ. On the other hand, the amount of patronage which any one company can confer in a small town is not sufficient to establish the desired closeness of relationship between the physician and the home office. But let the entire business of this town be given to a single physician, who shall be known as the "Medical Examiner to the Associated Life Insurance Companies," and we believe there will no longer be any difficulty in securing the best medical examiners the country affords, and in infusing into them that sense of responsibility which "Secretary" misses so much in the average examiner. The position will then be worth having, and will no longer go a-begging, as it now sometimes does. In some instances, too, it will be within the power of the Association to establish a suitable physician in places where a competent and trustworthy medical examiner cannot be found; for the patronage which they can assure him will be sufficient to bridge over the first year or two of waiting. In some of the larger towns and smaller cities, the Association will probably find it to their pecuniary advantage to pay the physician a regular salary, and require him to hold insurance office-hours in some central part of the town. It is only by the adoption of some system like this that the companies can ever

* The writer has seen letters from agents, complaining that the applicants whom they had secured with great difficulty were rejected by the physician, simply in order that the risks might be placed in the company of which he was the regular examiner! If this be true, the company has only itself to blame for employing physicians who are willing to act the double part of agent and examiner, even at the expense of their consciences.

expect to educate a large number of experts in the selection of lives. As matters now stand, almost every physician tries his hand at this, the most difficult of medical problems, and, as a consequence, few only become really skilled in the work.

But, while we believe that the proposed change is both desirable and feasible, we can readily foresee at least some of the difficulties in the way of its accomplishment. The majority, if not all, of the companies composing the chamber have pretty full lists of physicians whom they are now in the habit of employing as medical examiners. Some of these lists have been made out with great care and impartiality, and at no small pecuniary outlay; others have been made out with no special care, and have cost little or nothing. When the common list is finally made out, it will be found that it corresponds pretty closely with that upon which a great deal of money and time has been spent. This being the case, it is natural that the companies which have already spent their thousands in securing the services of the best physicians, should object to entering into any coöperative organization in which they are to stand upon the same footing, as regards expenses, with other companies which have spent little or nothing. This objection can be overcome, we believe, by assessing the companies at the very outset according to the following principle: suppose the Association's list for the State of Rhode Island to be completed. Out of the twenty or more companies composing the chamber, it will be found, for example, that five are doing business in that State, and that in a given town two of the five companies are already in the habit of employing the Association's examiner. If we estimate the average expense of obtaining an examiner's name at \$5, the three companies which have not already employed the examiner in question should be assessed \$1 each, and \$1.50 should be placed to the credit of each of the other two companies.

The second great difficulty which the Chamber will have to overcome will be the framing of some working plan or machinery, through which the list of medical examiners can be kept full, can be quickly enlarged when necessary, and at the same time can be made easily available to all the members of the Chamber. This will be a difficult task, but we sincerely hope that the committee having this matter in charge will not be frightened by these difficulties into an entire abandonment of the plan. In the hope of stimulating others who are interested in the subject to express their views upon the proper method of organizing such a work, we shall give a hasty sketch of the plan which seems to us at least feasible, if not the best.

As a preliminary step, let the companies represented in the Chamber bring together their lists of medical examiners, compare notes, and determine upon a list which shall serve as at least the foundation for the roll of medical examiners to be employed by the Associated Life Insurance Companies. When the list is completed it will be necessary to entrust some one with the duty of managing it, as it will require constant revision. Each of the different States of the Union should next be organized into districts, with a medical supervisor or referee to be responsible for the appointments needed at any time within the limits of his district. These referees or supervisors should be men of high social and professional standing, men who will take a pride in conferring the patronage at their disposal upon those of their brethren who are best fitted to fill the positions.

The foundation list of examiners once completed, the States properly districted, and the district medical supervisors all appointed, and have we not at least an

outline of an organization such as we believe the Chamber contemplates? But it is not difficult even to fill in some of the details. Thus, for example, the X. Y. Z. Company has at the outset been furnished by the Central Bureau with complete lists of examiners for the States of Ohio, Indiana, New Jersey, Pennsylvania, and New York. Its business does not yet extend beyond these States. After the lapse of three or four months, an agency is established in Connecticut; whereupon the Company writes at once to the Central Bureau for a list of medical examiners for that State, and receives by return mail the names and addresses of 100 or more physicians. The expense for this information ought not to exceed at the very most fifty to seventy-five cents per name. Then again, every week or every two weeks the Central Bureau should issue to the X. Y. Z. Company a notification of the changes (deaths, removals, new appointments, etc.) which have been made in the lists of the States in which the Company is doing business. Besides these weekly or semi-monthly reports to the different companies, the person in charge of the Central Bureau should make a monthly report to the executive or financial committee of the Chamber. But here we are encroaching upon territory which belongs more properly to the business man than to the physician. Enough, however, has been said to show that the plan of organizing a large body of medical experts—or at least men who in time may become experts—is neither Utopian in character nor involved in difficulties which a committee of physicians and business men might not readily overcome. Essentially the same plan has been tried with good results by at least three or four companies, but the expense connected with it has been so great as to frighten other companies from following the same course. The present co-operative movement, if carried into effect, would reduce the pro-rata expense to a comparatively low figure, while, on the other hand, it would very greatly increase the value of the examiners' services to the companies employing them, by impressing them with a greater sense of responsibility, by rendering the position more lucrative and hence more desirable, and, finally, by giving them more frequent opportunities for acquiring the experience necessary to make them experts.

MORTALITY OF NEW YORK.*

By PROF. CHARLES F. CHANDLER, Ph.D.

In studying sanitary questions, one of the first points is to get at the facts, and for this reason what are called vital statistics are carefully collected, collated, and studied in order to ascertain the facts connected with death and disease.

In 1872 the number of deaths in New York was over 32,000 in a population of 1,000,000, or as it is technically spoken of, 32 per cent in the thousand. It is important to know how this death-rate is distributed among the ages, as it is the first point in determining how to prevent death, and we find to our horror that nearly one-half the deaths are of children less than five years old, showing that the causes leading to this great death-rate are dependent not so much on the action of persons themselves as of those who should care for them. Between the ages of five and twenty $12\frac{1}{2}$ per cent. more die, so that before reaching manhood, 62 per cent. of our population dies. For the remaining period it is distributed more equally: from twenty to twenty-five, about 5 per cent.; from twenty-five to thirty, 5 per cent.;

* An extract from an address recently delivered in this city, and reported in full in the *N. Y. Tribune*.

from thirty to thirty-five, about 5 per cent.; from thirty-five to forty, a little over 4 per cent.; from forty to forty-five, a little less than 4 per cent.; from forty-five to fifty, 3 per cent.; from fifty to fifty-five, the percentage is 2½; from fifty-five to sixty, 2½; from 60 to 70 about 2, and from 70 to 75 a little over 1 per cent. Then the number falls off. In fact, all but 5 per cent. die before they reach the age of threescore and ten. While the mortality in New York is 32 in 1,000, we have reason to believe that under favorable circumstances the inevitable mortality should not be more than 17 in 1,000; that the mortality is nearly double what it might be if everything we could do were done to diminish it.

But it is not merely the persons who die who are to be mourned. They are not the most unfortunate people in the community. Those who are sick and cannot die are frequently much more to be pitied, and if we carefully study the ratio of sickness to death we shall find for every person who dies there are two persons sick all the time in every community. If 32,000 die in New York per annum, 64,000 are sick all the time; that is, sick for the entire year. But for the deaths from day to day it is estimated that for each death there are about 30 cases of sickness. In Manchester Dr. Playfair found it was 23 for each death, while the average duration of each sickness is about 20 days. A careful record was kept not long ago in the Metropolitan Police in regard to the amount of sickness. The Metropolitan policemen were selected by physical examination, and were as healthy a body of men as could be got together. They were governed also by tolerably strict and severe rules, by which their health was protected to a considerable degree.

It was found by a careful investigation over a period of four years, from 1864 to 1867 inclusive, that the total number of deaths in the force amounted to only 12½ in a thousand per annum; that is, it was only a little more than one-third as much as the average death-rate for the entire city. It was found, however, that the average sickness was 11½ days per annum. Every man in the force averaged a loss of 11½ days every year. Now taking the rate of 12½ deaths and multiply it by 30, the usual number of sicknesses, there must have been on an average 370 cases of sickness constantly, and multiplying this by 20, the number of days' average sickness, we have in this force of a little over 2,000 men a loss of 7,400 days by sickness. But we find that they actually lost 11,000 days by sickness, which would amount to 3¼ years of labor. The value of the time actually lost by that little body of men by sickness was \$37,000 a year.

The diseases commonly known as contagious do not cause so large a proportion of deaths as is generally supposed. For instance, in the year 1872 the city suffered from a very severe attack of small-pox, and a larger number of deaths ensued than are likely to occur again. There were nearly 1,000 deaths out of 32,000 by small-pox. Typhus and typhoid and scarlet fevers, measles and diphtheria destroyed 1,000 or 2,000 in the aggregate. Of course it is not claimed that anything like all the cases from sickness from special causes can be prevented, but a large proportion of the sickness, and a large proportion of the deaths, occur from bad or insufficient food, bad air, bad water, and imperfect shelter. Poverty is one of the most frequent causes of sickness, as sickness is one of the most frequent causes of poverty; but climate and topographical influences produce disease. There is one cause of disease, however, that cannot be too frequently mentioned, because it is entirely within our own control. In the year 1872 there were 314 deaths from alcoholic influences in this

city, of which over 100 were from delirium tremens. No plan yet seems to have been successful in coping with this, which is one of the greatest evils of the present day.

A word in regard to the causes of disease again.

It has been demonstrated that disease is preventible, and the plague that formerly desolated large countries scarcely appears now. In the year 1592, in London, 21,000 persons died of the plague; in 1603, 36,000; in 1625, 45,000; in 1665 no less than 68,000 persons were swept away in a single year, twice as many persons as die in New York, and this was when London was a comparatively small city. In the little island of Iceland, in the year 1707, 18,000 people died of small-pox out of a population of 50,000. Now this is one of the most easily prevented of all diseases, and it is not probable that there will ever be another serious outbreak. In 1870, 900 persons died in New York, but in 1872 a vaccinating corps was sent out and 100,000 persons were vaccinated—as many as would permit it, being vaccinated free of charge. Yellow fever is equally under control. One of the best illustrations of the possibility of investigating a disease, and of controlling it, is presented by the case of the silkworm. The silkworm forms one of the most important elements of wealth in France. Some years ago a disease broke out among the silkworms, and the caterpillars which make the silk were covered with dark-colored spots; their ability to work suddenly stopped, and the silk industry of France was almost entirely destroyed. A great French chemist investigated the matter, but he at first found scarcely anything to detect in the little worms the character of the disease or its presence until it manifested itself by destroying the worm, but he subsequently discovered in the moths—the previous stage of development—the cause of the disease, or the indications of it, and he found that he could distinguish those moths afflicted with the disease, and that by proper isolation and treatment the disease could be eradicated and controlled, and so this important industry was saved to France.

Comprehensive inquiries have demonstrated the fact that thorough drainage of a place is invariably followed by a decrease in consumption, typhoid fever, and rheumatism. The researches of the English Sanitary Department and recent investigation undertaken by the State Board of Health of Massachusetts, have shown that the average result of drainage improvements, when thoroughly carried out, after a few years, is to reduce the mortality by consumption 15 per cent. and that the reduction continues. At the same time the other causes of mortality are diminished from one-tenth to one-half per cent.

In England a thorough system of drainage and introduction of good water was tried in a number of towns, and it was found that the improvement to the little town of Dover, of 23,000 inhabitants, resulted in 7 per cent. of the mortality being reduced. In Croxdon the reduction was 22 per cent.; in Salisbury, 20 per cent.; in Cardiff, 32 per cent., and in Newport 32 per cent.; in other words, one-third of the deaths were prevented in this community by the introduction of a proper system of drainage and fresh water. While the general mortality was diminished in this degree, the mortality from special causes was diminished to a much greater degree.

Prof. Chandler gave from these facts the inevitable deduction that health is the workingman's capital. The emigrant is worth \$1,000, and the able-bodied man worth several times more. He pointed out that the sanitary improvements in England increased the average length of lives in a geometrical ratio.

Original Lectures.

CLINICAL LECTURE

UPON CASES OF

UNUNITED FRACTURE, AND A CASE OF DEFORMITY PRODUCED BY MUSCULAR CONTRACTIONS.

BY LEWIS A. SAYRE, M.D.,

PROFESSOR OF ORTHOPEDIC SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Phonographically reported for THE MEDICAL RECORD.]

GENTLEMEN—The two cases which I shall first present to you to-day belong to a class of accidents of somewhat frequent occurrence, and it is proper that you should obtain some knowledge regarding their management. One of these patients has at present an ununited fracture of the femur, and the other has had the same condition of affairs, but union has taken place, as you shall presently see.

UNUNITED FRACTURES.

CASE I.—This case, when it first came under observation, presented all the features of an ununited fracture of the femur. It had been present some seven months, and in a man having good health and about the middle period of life. The only means resorted to in this case for the purpose of securing union of the bone was a most thorough manipulation, with the view of exciting inflammatory action at the point of fracture, and subsequently dressing it in a fixed apparatus, plaster-of-Paris. The case was treated by Prof. Wood, of this college, and fortunately the result obtained is all that could be desired. Firm union has been established, as you see, when a bending force is applied to the shaft of the bone. It will be noticed, as the patient is lying upon the table, that he is unable to raise the limb while it is held in the straight position. The reason for this is, the shortening which has attended the union of the bones has so approximated the origin and insertion of the muscles, that the requisite amount of muscular power has not yet been restored, to enable them, with their slack-rope, to raise the weight of the limb. The man, however, is now able to walk a very little; and the more the limb is exercised, the more rapidly will a complete recovery be effected.

CASE II.—The second case of this kind I bring before you, gentlemen, is in the person of this man, of middle age, who has heretofore always been healthy. Nearly six months ago he was thrown from a horse, and received a double fracture of the right femur. The lower fracture was at the junction of the middle and lower thirds, which has united; and the upper fracture was at the junction of the middle and upper thirds, which has remained ununited.

There is some shortening present when the limb is measured in the position it naturally assumes. Now, if the law laid down by some is true—namely, that shortening must necessarily take place before a fracture can unite, a certain amount of the shortening present in this case can be accounted for from the fact that the lower fracture has united.

The law, however, that shortening must necessarily attend the union of a fractured bone is incorrect, as can be satisfactorily proved by practical demonstration.

Before proceeding to the consideration of the case immediately before us, I will direct your attention to

some of the rules which should govern you in the treatment of fractures.

The first rule is, that in the treatment of all fractures of bones, wherever they may occur, extension and counter-extension are to be applied in the proper direction until the muscles have adjusted the broken fragments with perfect accuracy, and after that *retention*.

Second. Extension should not be made beyond the point of securing accuracy of adjustment; for extension carried beyond that point is abnormal, and the tendency of the muscles is to rebel at once. Consequently, they manifest their excitation by reflex contractions, which are simply endeavors to get away from this over-extension. When extension has been carried sufficiently far to secure accuracy of adjustment between the fragments of broken bone, and *no more*, all the blood-vessels, nerves, fasciæ, and muscles are brought into precisely the same relation with each other as existed previous to the occurrence of the fracture. Circulation can now be carried on in a normal manner, and the chances for bony union to occur are very much increased.

Again, extension carried beyond the normal amount, and too long continued, produces either a constant irritable action of the muscles, or paralysis of the muscles; hence the practice of treating fractures by continuous and prolonged extension should be condemned.

If the muscles are retained too long in a fixed position there may be produced an absolute relaxation, consequently *lengthening* of the limb. It is altogether probable that this cause has been at work in the present case, and has given rise to non-union at the upper fracture; for, as you see, it now requires but a moderate amount of extension to bring the foot down to a point *below* the foot of the opposite limb, showing that the muscles, to a certain extent at least, have become paralyzed. Now you will see the impotence of the law laid down, that shortening must always take place if union is effected. There should be shortening instead of lengthening of the limb in the present case, for union has taken place at the lower fracture.

The muscles, doubtless, have become paralyzed in consequence of the long-continued extension which was maintained in the earlier treatment of the case.

These remarks are not made in any spirit of censure, but simply with a view of pointing out to you the liabilities in such cases, in order that you may avoid a like error.

Without further general remarks, we come to the question, What is to be done with this false joint?

The relaxation of the muscles is such, that the ends of the fragments can be separated nearly an inch. The false joint has existed so long, that in all probability the ends of the fragments have become tipped with cartilage.

The only means by which a union of the separated fragments can be effected is, in some way to excite a fresh attack of inflammation between and around their extremities. How is this to be done?

Sometimes you may succeed in establishing a sufficient amount of inflammatory action to cause union by merely rubbing the ends of the fragments together quite forcibly, as was done by Dr. Wood in the case just presented, and subsequently placing them in a fixed apparatus. Another method of exciting inflammatory action is by passing long needles down upon either side of the bone at the point of fracture, and sending a current of electricity over them. The current may be continued gently for five or ten minutes at each sitting, until sufficient inflammatory action has

been developed. This is a somewhat vigorous means for exciting inflammation, and in case too high a degree of new action is excited, it is to be combated with rest, cold, and the application of leeches. In general, however, if carefully applied, not much trouble follows; and in some instances, manipulation and electricity can be combined without producing any unpleasant effects. Another method which has been practised, is to cut down upon the bone, saw off the ends of the fragments, bring them together, and hold them in apposition by means of wire passed through holes drilled in the extremities of the fragments. This operation, in the present case, would be hazardous, on account of the close proximity of the fracture to important vessels in the thigh, and will therefore be deferred until the necessities in the case absolutely demand it. Another method consists in cutting down upon the bone, and boring several holes obliquely through the broken extremities, and removing the boring instrument in such a manner as to leave the chips within the holes. This may be sufficient to excite the requisite amount of inflammatory action.

Another method which has been recommended, is to cut down upon the bone, bore holes through the end of one fragment into the other, and afterwards hold them in apposition by means of ivory pins, trusting to those to excite an inflammatory action.

I do not approve of this latter method of operation; for it leaves foreign bodies within the bony structure which may subsequently do harm.

By whatever means it shall be accomplished, the principle is to excite inflammatory action in and about the ends of the bone, and when sufficient amount of inflammation has been developed, place the limb in a position of absolute rest, with the fragments of the bones in immediate apposition, and then maintain a certain amount of compression of the fragments against each other, rather than extension. It is not always practicable to avoid shortening in this class of cases, and the patients may very often have reason to be satisfied if union is effected at all.

In the present instance I shall first try what can be accomplished by manipulation. If this shall fail, then the galvanic current will be added. If, by thorough manipulation, I can succeed in sand-papering the ends of the bones, manipulation will probably accomplish the desired result.

(The patient was then placed upon the table, and the fracture subjected to the most thorough rotary and circumductory motions for the purpose of "grinding off the polish.")

This manipulation will be repeated once or twice a day until there is considerable evidence of the presence of inflammatory action.

Feb. 25th. Manipulation and galvanism have both been employed during the past week, and to-day the temperature of the limb is considerably elevated, the surface over the fracture is somewhat reddened, and a long plaster-of-Paris splint will be applied, reaching from the toes of the affected limb to above the ilium. The patient will now be placed upon the apparatus devised by Dr. Figueira, house-surgeon, for securing extension and counter-extension, and maintaining the lower portion of the body in a position somewhat elevated from the table while the fixed dressing of plaster-of-Paris is being applied.

You will please to notice the manner in which the leg is prepared for the application of extension. Dr. Figueira, after having applied a couple of rollers over the leg, applies upon each side a strip of wire gauze three-fourths of an inch wide or so, extending from the upper portion of the leg to some inches below the

foot. The strips of wire gauze can be doubled together and fastened, and when the dressing has set for a few minutes, all the extension necessary can be applied without doing injury to the limb. This is a very valuable suggestion.

March 10th. The patient has been travelling around the wards every day since the application of the fixed apparatus.

CASE III.—*Muscular Contraction. Deformity simulating Hip-joint Disease.*—This patient, gentlemen, has been brought to us from an adjoining State, with the expectation that we will determine what the condition is from which she is suffering.

She is aged thirty years, and the mother of a family. Previous to one year ago she had enjoyed an average degree of health. Family history good.

One year ago she suffered from typhoid fever, and in the progress of the case bed-sores were developed over the sacrum.

After the second week of the disease she was inclined to lie with the thighs flexed upon the body, and the legs flexed upon the thighs. There was no diarrhoea during the progress of the case.

When convalescence was established, and the patient began to get up, she found that her limbs were excessively weak, but that the left was much weaker than the right. Contractions immediately began to follow, and have gradually increased until now, when we find the left leg very much in the position assumed in the third stage of hip-joint disease.

How are we to determine whether it is hip-joint disease or not? While the patient is lying upon her right side you will notice that the left knee is about four inches above the other; that is, the limb is *apparently* shortened to that extent. The left limb is also strongly adducted, and the thigh is carried across the thigh of the right side.

The next thing to be determined is, whether the shortening which is present is apparent or real.

If it is due to distortion of the pelvis, when the pelvis is placed in proper relation with the trunk it will at once be removed. In order to place the trunk and pelvis in normal relation, place the patient upon the back. Then two lines, one drawn from the ensiform cartilage to the centre of the symphysis pubis, and the other from the anterior superior spinous of one ilium to the other, will cross each other at right angles. This will be the case if the pelvis is placed in this position, and held firmly fixed, with the spinous processes touching the table, and, if the shortening is apparent, it will at once be removed. In this instance, as you see, the shortening is at once removed, and is, therefore, only apparent. Crowding against the lower extremity of the femur produces no pain whatsoever, which would not be the case if disease of the hip-joint were present. Pressure upon the trochanters causes no pain. Abduction causes pain. Extension causes severe pain. The slightest flexion of the thigh relieves all pain at once.

If this were a case of hip-joint disease it would be necessary to slightly flex, and at the same time slightly extend the thigh in order to place it in the proper position to give relief from pain.

As it is, simply lifting the limb, giving it slight flexion, which approximates the origin and insertion of the psoas magnus and internal iliacus muscles, causes these muscles instantly to go to sleep, and all pain is at once relieved. Still further, if we would satisfy ourselves beyond question, which is well to do when possible, we should employ Nelaton's test. If a line is drawn from the tuberosity of the ischium to the anterior superior spinous process of the ilium upon the

same side, it will pass directly over the trochanter major, when the bones of the thigh and pelvis are in their normal relation.

If the head and neck of the femur are absents, as is the case in advanced hip-joint disease, the trochanter would be above this line.

If there is fracture of the neck, causing displacement, the trochanter would be above the line indicated. Now, applying this test in the present case, it is found that the line passes *directly* over the trochanter. It is evident, therefore, that the head and neck of the bone are in proper relation with each other and with the acetabulum. This deformity, therefore, is due to some condition of the muscular attachments rather than to some disease affecting the bony structure. Our conclusion then is, that the adductor and flexor muscles of the thigh have been inflamed from some cause, which has resulted in the firm contraction now present. We arrive at this conclusion from the following facts: that no evidence of hip-joint disease or other disease of the bony structures is present; that the moment these two sets of muscles are placed upon the slightest stretch, pain is at once developed. Also, the additional, and not less important fact, that the moment the limb is placed in a position which relieves all tension and permits these two sets of muscles to go to sleep, all pain at once ceases.

The question now arises, What is to be done for our patient?

Constant, unremitting extension by means of elastic force will restore the parallelism of the limbs; passive movements will restore *active* movements at the joints, and the joint action of the two, carefully applied and gradually increased, will establish a perfect cure.

This belongs to the class of cases that receive great benefit from the so-called *massage*, the means being orthodox, while the name is a humbug. Every physician and surgeon from time immemorial has employed this manual manipulation, but it has now come out under a new guise, simply to give the impression that something new has been devised and developed in a new and mysterious manner.

This is removal of the deformity by means of gradual extension.

There is another method of removing the deformity and overcoming the muscular rigidity, and that is to place the patient under the influence of an anæsthetic, and give rapid and forcible movements to all those joints which have been rendered useless for so many months by muscular contraction and perfect rest. When free motion has been established in that manner, the patient is to be placed in bed, adhesive plaster applied to the limb in the manner used for extension and counter-extension, and just sufficient extension employed to maintain the limbs in their proper position. Then guard against the inflammatory action which may follow the rapid and forcible movements which have been applied for breaking up all resistance to free motion, by the firm application of a roller bandage, perfect rest, and, if necessary, the application of cold to the parts involved, as already alluded to in connection with a former case. But the question may arise, Will it not be necessary to cut some of these contracted tissues before complete cure can be effected?

If, while the patient is under the influence of an anæsthetic, we place these contracted tissues firmly upon the stretch and retain the tension, and then make an additional point of pressure with the thumb or finger upon the tissues thus made tense, and reflex contractions are excited, the contracted tissue must be

cut or forcibly ruptured, whether it be muscle-tendon or fascia, before any benefit will follow treatment.

If, on the contrary, reflex contractions are *not* excited by the additional point of pressure made in the manner indicated, the application of constant elastic force, gradually increased, will cause the contracted tissues to yield sufficiently to give complete recovery without resorting to the cutting or rupturing operation.

If, upon the one hand, these contracted tissues are kept in a constant state of tension by an extending force, without cutting or rupture when the additional point of pressure produces reflex contractions, an irritable fever will most likely be developed, which will sooner or later wear the patient out if the extension is continued.

If, on the other hand, the case is left to itself, structural changes will inevitably be developed in the muscles, leaving the deformity beyond all hope of correction.

This is therefore a case, gentlemen, in which a vast amount of damage may be done by injudicious interference; one in which certain inevitable results are to obtain, if left alone; and one in which much good can be accomplished by the proper application of elastic force.

With proper management, we may reasonably expect that this woman will be able to walk within one year.

Original Communications.

AN AGGRAVATED CASE OF TRIFACIAL NEURALGIA

SUCCESSFULLY TREATED BY THE DEEP INJECTION OF CHLOROFORM.

By J. B. MATTISON, M.D.,

CHESTER, N. J.

To Prof. Roberts Bartholow, of Cincinnati, is the profession in this country, and the world, for aught we know to the contrary, indebted for the discovery of the astonishing result produced by the deep injection of chloroform in those cases of the most agonizing neurotic distress known to suffering humanity—*tic douloureux*, or, as Trousseau styles it, "*tic épileptiforme*."

The peculiar obstinacy and almost hopeless prospect of effecting a radical cure in typical cases of this disease is well known to the profession—medical and surgical interference having been resorted to in vain—and any discovery which seems to add another weapon to our armamentarium in the struggle with this well-nigh invincible disorder must be hailed with delight, especially by those unfortunate enough to be numbered among its tortured victims. Such an addition we believe the deep injection of chloroform to be; a belief based on the wonderful results of cases by Dr. Bartholow, and a well-marked case very recently under our observation.

In a communication on this subject lately given to the profession,* Prof. B. explains the *modus operandi* of its action and the details of the operation so thoroughly that it remains for us merely to confirm his statements by citing the circumstances and termination of the case we have to present.

C. D., whose history as an excessive consumer of morphia, hypodermically, was given to the fraternity some months ago,† applied to us, Dec. 18th, for the

* Med. and Surg. Reporter, No. 871.

† Ibid., No. 821.

relief of an aggravated attack of trifacial neuralgia from which he had been suffering for several days. By referring to the history aforesaid it will be noted that the first manifestation of his neurotic trouble was in this particular locality, where it continued for two years, and then suddenly attacked his left hip, remaining there most of the time for twelve years, till its return to the right infra-orbital branch of the fifth pair.

The onset of its recurrence in the original site was sudden, and without any discoverable determining cause. The paroxysms followed each other at intervals of four to six hours at the beginning of his attack, which gradually diminished until, at the time of his visit, they were occurring every few minutes. During the seizure the muscles of the affected side twitched convulsively, the face was distorted, and the patient, laying hold of anything within reach, groaned aloud in the agony of his distress. Such excruciating suffering we never witnessed.

He had been using his morphia freely, but so intense was the pain it produced no effect. During the four days subsequent to his visit we employed various remedies with the hope of affording him relief, but without any satisfactory result. Morphia, subcutaneously, in increased amount, reaching at one time five grains at a dose, without any benefit whatever; atropia, hypodermically; potass. brom. in large doses; hyoscyamus, sinap., blist. to the nucha, and, lastly, galvanism, which seemed at first to cut short the paroxysms, but did not lessen the frequency of their coming. Finally this failed, and the man became desperate, threatening to destroy himself if relief were not obtained.

At this juncture, when the paroxysms were becoming frightfully frequent, with no abatement in their severity, we resorted to the deep injection of chloroform. Charging the syringe with one-third of a drachm, Nichols' manufacture, the needle was inserted under the upper lip, pushed upward until its point rested near the infra-orbital foramen, and the chloroform slowly injected. Its presence instantly gave rise to a paroxysm of unprecedented severity, which continued about four minutes, followed by a feeling of anaesthesia of the parts in which the chloroform was introduced, decided drowsiness, and *entire subsidence* of pain. No giddiness was produced, and the gait was unaffected. A distinct, puffy swelling soon made its appearance at the site of the injection, which did not entirely disappear for several days, but no inflammation was excited, consequently no abscess ensued.

The relief from suffering continued complete for one hour and fifty-five minutes, the sopor, meanwhile, being very decided, and the patient acting much as if under the influence of moderate general anaesthesia. At the expiration of this time he had a slight seizure; one half hour later another, very mild, and thirty minutes after, on opening a door to get into the outer air, he experienced one of considerable severity. The drowsiness continuing, he was directed to bed, and on visiting him two hours subsequently, we learned he had passed through two paroxysms, one slight, the other somewhat severe. The numbness of the lip and cheek was marked, and the drowsiness continued. This was at five p.m. of the 22d, from which date until the afternoon of the 27th he remained entirely exempt from pain. Calling again that evening (22d) and finding him still sleepy, he was ordered chlor. hyd. grs. xx. every half hour until decided effect should be produced. Two doses were taken, when he fell asleep and slept for five hours. Forty grains additional were then administered, same dose and interval as before, when he again fell into a profound slumber, which

continued for ten hours. On awaking he arose, made his toilet, an operation he had been utterly unable to accomplish for days previous, on account of the horrible pain it excited, and walked to our office, a considerable distance, without difficulty. He was still very drowsy, and we again recommended him to bed; sleep being secured the following evening by the free use of chloral. The next day he complained of chilliness, great debility, and a sense of general discomfort. He was now placed upon the use of the following tonic:

R. Magnes. sulph.		3 ss.
Mangan. "		3 ij.
Fer. "		3 ij.
Quin. "		3 i.
Acid dil.		5 ss.
Aq. ad.		5 viij.
M.		

S. Tablespoonful in wine-glass of water thrice daily, and in addition, strych. sulph. gr. $\frac{1}{4}$ hypoderm. ter die, with atrop. sulph. gr. $\frac{1}{10}$, subcutan. hor. somn. Chloral was employed to secure sleep at night, and a generous diet ordered, beef-tea and coffee being freely given.

Finding, after a few doses, the above tonic ineligible on account of its bulk, we substituted

R. Elix. phos. fer. quin. et strych. (Wyeth's.)

Dessertspoonful three times daily, continuing the strych. and atroph. hypodermically as before.

The patient kept his bed most of the time until the afternoon of the 27th, when, in washing his face, he experienced a paroxysm of the trifacial pain, of decided severity, which continued three minutes, but without any of the spasmodic muscular movements attending the previous attack. Two hours later he had another seizure, of diminished severity, since when, until the date of this communication, a period of nearly four weeks, he has been entirely free from suffering.

The second tonic was continued one week, when he was prescribed the following:

R. Quin. sulph.		gr. ij.
Tinct. fer. chlor.		gtt. xxx.
Liq. potass. arsen.		gtt. x.
M.		

S. Take at a dose, diluted, after each meal, the other remedies to be continued.

Under this treatment his appetite returned, strength increased, and his general condition so improved that at the expiration of seventeen days he was able to resume his vocation.

The plan of treatment pursued subsequent to the injection of the chloroform demands, perhaps, some explanation. It had a threefold object in view: recuperation after the prolonged bout of pain; toning up his nervous system to eradicate the tendency to neurotic disorder; and the making amends for the withdrawal of his long-accustomed stimulus.

As to the first point, the result of the case sufficiently proves its success.

Concerning the second, a marked decrease in his sciatic suffering (for, a few days after the relief of his trifacial trouble, pain returned with great severity in his left hip) made itself manifest in less than a fortnight.

Regarding the last point, we may state that, taking advantage of a peculiar combination of favorable circumstances (of which more may be said hereafter), we withdrew *entirely* his morphia, with the object of

emancipating him from the drug which for more than six years had enslaved him.

The effect of this particular movement is still in abeyance, a sufficient time not having elapsed to enable us to speak *positively* as to a radical result.

This much, however, can be said: *not one particle of morphia* has entered his system since the chloroform injection (at this date, more than four weeks); his desire for it is a thing of the past, the craving subsiding *entirely* at the expiration of three weeks; so that we have strong reasons for hoping we shall be able to report at no very distant day an accomplishment complete and satisfactory.

In a retrospect of this case, one or two additional points present themselves for reflection. The first relates to the amount of chloroform injected. We entertain the opinion that had the quantity been larger the subsequent diminished paroxysms would not have been experienced. Should a similar case present itself, *one-half* a drachm would be the *minimum* injection.

The intense pain produced by the diffusion of the chloroform suggests the propriety of a previous resort to very moderate *general* anaesthesia, with a view of avoiding this exceedingly painful complication.

To sum all, the astounding results in every case, to our knowledge, recorded, mark the injection of chloroform as a new era in therapeutical advancement, entitling its discoverer to the lasting gratitude of a class of patients to whom, heretofore, in many cases, no measure of relief has proved competent to cope successfully with their painful disorder.

I may add, the man has had no return of his "tic;" his reformation as to the opium habit seems *complete*, not having had an atom of morphia since the chloroform injection. He has, too, been *entirely exempt* for *weeks* (something unprecedented during *fifteen years'* experience) from his sciatic trouble, making, in all, a very interesting case, with an eminently satisfactory result.

ACUTE INSANITY.

By HORATIO R. BIGELOW, M.D.,

HARTFORD, CT.

In the paper read at the Forty-first Annual Meeting of the British Medical Association, Dr. Sankey expressed a doubt of the existence of any such disease as primary acute mania, because the cases which had come under his notice as instances of this condition were—

1. Cases of general paresis in the expansive stage.
2. Secondary attacks of recurrent insanity.*

That these cases of primary disease are extremely rare, that in the literature of insanity other forms of cerebral aberration are very frequently confounded with it, is very true; but that acute mania *never* obtains primarily, is an assertion which would find but little corroborative evidence in its support from the records of our various insane asylums.

In the vast majority of instances the "d'élire aiguë" is a mere symptom of an antecedent condition, which had manifested itself in such wise as to be inappreciable by friends; or the symptoms may have been regarded as eccentricities of character; or the unwonted melancholy, misanthropy, or undue exaltation, as the normal deviations from a healthy standard. It is from meagre, insufficient histories, from a lack of thorough investigation, and from a want of discriminating diagnosis, that cases of acute melancholia, mania with

exaltation, recurrent mania, and some stages of paresis, are confounded with each other and with acute mania.

An intellectual differentiation of symptoms, the balancing of statistical facts, the deductions drawn from a searching history of the patient's life, surroundings, and relations, with a scientific employment of physical means, will usually insure a correct and reliable diagnosis.

Acute mania is most frequently confounded with the violent stage of acute melancholia; hence we would draw the attention of the profession to the salient points of difference between the two.

Acute Mania.—This condition has no period of incubation, and may be accompanied with absolutely no history of previous departure from a normal condition of health, with no unusual manifestations of thought or action, and without any trace of hereditary taint. It seizes its patient suddenly, while engrossed in the vocations of his daily life, never while asleep. It affects men oftener than women, the percentage out of twenty cases observed being sixty-five in favor of the male sex. The most susceptible age in the female is between twenty and twenty-five years—in the male between twenty-five and thirty years. Its tendency is towards death from exhaustion, the percentage of fatal terminations being greater than in acute melancholia. There is great incoherence, restlessness, violence, and seeming unconsciousness to surrounding circumstances. There is a copious secretion of viscid saliva; constipation generally present. This stage of activity continues two or three weeks, to be followed by a condition of extreme prostration. There is no undue, persistent tension of a dominant idea, giving rise to a positive unaltering delusion as in melancholia, but a marked incoherence of expression, with no intelligible or logical continuity of expression. The exciting cause of the disease seems to destroy the harmonious transference of residua in the higher centres of the brain, the mind being unable, from instability of nervous action, to keep before itself the contemplation of any simple fact. The hallucinations and delusions are fleeting and unstable. There is less perversion of the muscular sense than in melancholia, and the manifestations of this disorder of the motor centres are not so persistent and coherent. The attack is progressive in character.

As will be seen from the table, the ophthalmoscope reveals most frequently a condition of hyperemia. Out of the twenty cases, fifteen presented this congestive aspect of the fundus oculi. Of these the majority were in a state of intense hyperemia, obscuring the regular, sharply defined periphery of the papilla, and destroying its pinkish hue. Palpation sometimes distinguishes an over-distention of the eye—hemipopia; megascopia may be present; normal acuity of vision lessened.

The breath has an unpleasant fetor. The skin is dry, hot, and parched. The urine is lessened in quantity, containing an undue amount of phosphates. Faces dark and of very offensive odor.

In the stage of exhaustion, death often sets in very suddenly and unexpectedly. Finally, the post-mortem changes are generally of a characteristic nature. The ventricles usually contain a liquid resembling chalk and water; the arachnoid and cortical cells of the brain are "filmed" with a cloudy substance. The substance of the brain is congested, and when cut into shows numerous red punctuated spots.

Males, 13; Females, 7; Average age, 28½ years.

Average age, Females, 19½ years. Average age, Males, 33½ years.

Anæmia, 25 per cent.; Hyperemia, 75 per cent.

* British Medical Journal, Oct. 11, 1873.

Deaths, 5; Recovery, 13; Unknown, 2. In cases Nos. 3, 12, and 14, the Mania was not primary. In four other cases it is doubtful if the disease was primary, though the records called them cases of Acute Mania.

Acute Melancholia.—The period of incubation is characterized by some changes in the patient's manner of reaction to surrounding circumstances. He may shun the society of his friends and family, become addicted to morbid introspection, and seek seclusion to gratify the desire. The hopeful part of his being becomes nil, and he views the occurrences of life in the most melancholy way; or sudden fears of his spiritual condition may possess him to the extent of overbalancing reason, and his melancholy assume a religio-maniacal type; or the concentrated application of his faculties in business speculations may have induced unwarrantable fears of approaching poverty; or the sudden accumulation of wealth may exalt cerebral action to a dangerous degree. Even in the minutest, most commonplace events of an every-day life, we may recognize slight abnormalities, which should excite our most serious apprehension. Generally close investigation will reveal some neurotic family taint, some eccentricity of conduct on the part of immediate relatives. It occurs most frequently in females. Out of twelve cases tabulated, seven were females, five were males. The average age of women suffering from this form of insanity was 24 years; of men, 39 years. The percentage of recoveries is greater than in acute mania. There is the same restlessness and violence as heretofore mentioned, but a greater suicidal tendency. There is a great, persistent tension of a single idea, usually of a religious or personal nature. The patient will imagine himself guilty of the unpardonable sin, or of some civil crime, or he will call aloud for reconciliation with an offended wife or child. The delusion is of the same unchangeable stamp. The sudden transition of ideas without logical coherence; the constantly changing hallucinations and illusions so characteristic of acute mania, are absent in acute melancholia. The patient may be entirely conscious of his surroundings, of his actions, and of his illness, yet will he not be convinced of the delusive nature of his fears, which are to him terribly true and real facts. The face in the stage of excitement is of exalted cast; the eyes wild and unsteady.

The "muscular sense" is greatly perverted. An idea, which in some instances may have reference to a previous condition, takes possession of the mind, to tyrannize over the cerebral outcome, and owing to the independent power of reaction, of the ideational centres to expend itself outwardly without the interference of volition, or the violent action may be the honest manifestation of what the patient thoroughly believes to be the real aggravation of circumstances by which he is surrounded. In the stage of exhaustion, the face changes to a depressed, woe-begone expression. The vital powers are at a low ebb. The patient is oppressed by the horrible condition in which he believes himself to be placed. He receives food very reluctantly.

The ophthalmoscope in the majority of instances will disclose marked anemia. In the twelve cases observed, eight presented appearances of anemia and four of hyperemia. As instances of both conditions occur, we should be guided to a correct diagnosis by a consideration of the history of the case, by a knowledge of the prodromic period, and by the measure of ideational derangement.

ACUTE MELANCHOLIA.

Males, 5; Females, 7; average age 30½ years. Average age, Males, 39½ years. Average age, Females, 24½ years. Anemia, 66½ per cent. Hyperemia, 33½ per cent; Deaths, 0; Recovery, 7; Unknown, 3; Dementia, 2.

As a typical case of acute melancholia, I would cite the following, now under observation:

R. McK., twenty-four years old, a Roman Catholic, born in Ireland, single, bricklayer by trade, having amassed by his own efforts a fortune of eight thousand dollars; maternal uncle was insane, patient is of temperate habits, with no prejudicial vices. Has always been rather reticent and nervous, with a prevailing passion for making money. Six or seven years ago he was affected by heat-stroke, since which time he has been a "little peculiar." About a week before coming under special treatment these peculiarities became more aggravated. He refused food and medicine, evincing suicidal propensities. His delirium was so severe that he was obliged to be held in bed. The disease has periods of remission. The ophthalmoscopic signs are those of intense hyperemia. There is a copious secretion of tenacious saliva; skin hot and dry; secretions retained. The frenzy is of a religious type, the patient constantly calling upon God, and mistaking his attendants for Jehovah, Judas, etc. His violence is extreme, but little, if any, perversion of the muscular sense. Convinced of the truth of his delusion, he will reason quite rationally thereon.

* Chronic meningitis of long-standing found at post-mortem.

† Thrombosis.

‡ Glioma.

* Edema of papilla.

† Crossed hyperemia: capillary injection of papilla.

There is no general incoherency of ideas, but a prominent fixed delirium.

The disease is now passing into the stage of exhaustion. The diagnosis in this case was based upon the history of the prodromata, and upon the character of the ideational derangement. The violence and delirium were quite as great as in acute mania.

Mania with exaltation can rarely be confounded with acute insanity by a discriminating observer. In these cases there is always an exciting cause and an unstable family history. There is great egoistic, self-important exaltation, a pompous gait and manner, and a large sense of personal importance.

If there were any doubt in the differential diagnosis of acute mania and general paralysis, the sphygmograph would decide the case. The tracings in these instances are peculiar: the upward line is short and abrupt, the descending line is long, wavy, and without an aortic notch.*

SEPARATION OF THE UPPER EPIPHYSIS OF THE HUMERUS.

By PROF. FRANK H. HAMILTON, M.D.,

NEW YORK.

CASE I.—Samuel Robuck, æt. 13, fell through a hatchway, July 9, 1868, striking on his shoulder. He saw a regular physician within five hours after the injury was received, who said that the arm was dislocated; and on the following day, under the influence of chloroform, he tried to reduce it. The doctor thought he had succeeded, and he then applied bandages to keep it in place. At the end of two weeks the doctor declined, for reasons which are not known, to have any further care of the case, and the patient consulted Dr. Voss, at the Dispensary. Dr. Voss detected the nature of the case and sent him to me to confirm his diagnosis. I found the upper end of the lower fragment projecting in front, and not united. The arm was shortened half an inch. I have not seen the patient since, and do not know the result.

CASE II.—Joseph Snellbach, æt. 16, fell backwards down a flight of steps, striking upon his back and arm near the shoulder, May 10, 1868, causing a separation of the upper epiphysis of the left humerus. Dr. — of this city, now deceased, saw the patient within half an hour, and supposing that he had suffered a dislocation of the head of the humerus, he attempted to effect reduction with his heel in the axilla, and without anesthetics. On the following day I found him in ward 16 at Bellevue. The house-surgeons were divided in opinion as to its character, some at first believing it to be a dislocation; others, with myself, recognized it to be an epiphysal separation.

All efforts at replacement proving ineffectual, splints were applied by my direction, and on the 15th of July the patient left the hospital with the fragments united, but overlapped at the point of fracture, the upper end of the lower fragment being in front of the upper fragment. The limb was shortened one inch, but its motions were free, and there was no reason to suppose that its utility was in any degree impaired.

CASE III.—C. H., æt. 19, living in a neighboring town, in the delirium caused by fever, fell from a third-story window, May 12, 1868. Two very intelligent and experienced physicians who were called, thought the boy had received a fracture of the acromion process, accompanied with a dislocation of the

head of the humerus, and they attempted to reduce it, but without success.

On the 2d of June following, three weeks after the receipt of the injury, I saw the patient in consultation with his physicians, and found a separation of the upper epiphysis of the humerus. The upper end of the lower fragment projected in front of the acromion process, appearing a little above the level of the process, and covered only by the skin. No union had occurred between the two fragments.

CASE IV.—John Davis, æt. 18, fell about 8 feet, Sept. 2, 1873. Of the three surgeons first called, Drs. H. and S. thought the boy had received a fracture; the third believed it to be a dislocation, and having placed the patient under the influence of ether, attempts were made to reduce it. The deformity not being relieved, I was added to the consultation. I found the shoulder a good deal swollen. The upper end of the lower fragment could be felt distinctly in front of the acromion process. At first, the surgeons informed me the broken end seemed just under the skin and almost ready to be thrust through, but the extension had made it retire somewhat. The end felt rough and serrated. While making extension I was able to detect a slight crepitus, or click. Employing Dugas' test, I found the elbow would rest upon the front of the chest. In short, the diagnosis was complete, and Dr. S., having taken charge of the case, applied one long splint, and a sling under the wrist, but not under the elbow. The fragments have united with very little deformity.

(This case was subsequently seen by Dr. Moore at one of my Bellevue clinics.)

CONTUSION OF THE LARYNX AND TRACHEA,

FOLLOWED BY IMMEDIATE AND COMPLETE LOSS OF VOICE, DYSPHAGIA AND DISTRESSING DYSPŒGIA, PARALYSIS OF THE LEFT VOCAL CORD: SLIGHT ANELIORATION.

(Read at a stated meeting of the New York Laryngological Society,)*

By BEVERLEY ROBINSON, M.D. (PARIS),

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, (DEPARTMENT OF THE THROAT), PHYSICIAN TO THE DEMILT DISPENSARY, ETC.

JOHN HALEY, mason, aged 60, came under my observation October 25th, 1873. Until October 5th had enjoyed excellent health. On that night patient says his son, a youth 17 years of age, returned home at a late hour in an intoxicated state, and when remonstrated with for his conduct struck him (patient) violently with his fist on the right side of the neck.

Immediately on receiving the blow, patient lost the power of articulate speech, and this condition continued during 4 hours; though he could make a faint, but indistinct and unintelligible noise, he was unable to pronounce a word so as to make himself understood. During this period he expectorated at intervals, and after painful paroxysms of cough, a moderate quantity of sanguineous sputa. The time mentioned having elapsed, his voice returned to him partially, manifesting itself in a low, hoarse whisper, and there were no more blood-tinged sputa.

During two days he could not swallow at all, and in attempts to perform deglutition violent attacks of

* The patient was seen by the members of the Society who were present at the meeting, and the accuracy of the diagnosis confirmed.

choking were caused, and the aliments introduced by the mouth were rejected—in part through the mouth, in part through the nasal passages.

At the expiration of that time, patient could swallow liquids,—with difficulty, however, and only while he held his nose tightly compressed between his index-finger and thumb.

Deglutition, to be accomplished, had to be performed rapidly, otherwise all fluids returned through the nose and mouth, and did not reach the stomach at all. When 10 days had passed by, patient began to swallow very soft, semi-solid substances, such as corn-starch or ground crackers, mixed with an abundant proportion of milk.

After this stage was reached no compression of the nose was found necessary, and he gradually became able to swallow articles of diet such as hashed meat, mashed potatoes, etc., until at present he can take any food which he could have taken previous to the contusion.

Great dyspnea existed for several days after the contusion, especially at night, when his breathing was noisy.

Actually, his respiration is much improved, although occasionally and after unusual exertion in walking, or talking, some difficulty of breathing is still appreciable.

The day following the assault the patient went for advice to the Northern Dispensary. He was under the care of one of the visiting surgeons to that institution nearly three weeks, and finally consulted me for the first time October 25th.

There was then moderate pain localized over the laryngeal region, evident difficulty of breathing, and, according to testimony of patient, notable dysphagia. I prescribed an inhalation of compound tincture of benzoin (ʒ i , aque ʒ o); to be repeated three or four times in 24 hours.

October 28.—Stridulous breathing, as in oedema glottidis, on inspiration; expiratory movement easy; voice very hoarse; aphonia more marked out of doors, where voice is reduced to faintest whisper. In doors, patient can sound his voice with some strength. This symptom has not varied since last seen; breathing somewhat improved.

On palpation, no signs are found of fracture or displacement of hyoid bone, or cartilages of larynx; no cough; sleeps well; expectoration in the morning on rising of pellets of thick mucus; auscultation of chest detects only a few disseminated, moist râles.

Larynx.—Physical examination shows that the left vocal cord is completely fixed; right vocal cord approximates well, in fact goes beyond mesial line. Both vocal cords are slightly congested; ventricular bands are considerably swollen and the upper orifice of larynx narrowed; no deviation of epiglottis or arytenoid cartilages from their normal position.

Treatment.—Rept. inh. benzoini—troch. ipecac.

Nov. 11.—No improvement in voice; feels very well in every other respect; still a few humid râles in chest, but no diminution of healthy tonality on percussion of chest-walls; vocal cords less congested.

Treatment.—Mist. quiniæ (gr. ij.— ʒ i .) and mist. expectorans (ipecac, acacia), etc.

December 7.—Voice is more distinct and stronger but continues nevertheless in a measure husky and disagreeable; some local pain remains and is made evident by very slight pressure over sternal notch on trachea. When in the open air the effort necessary to make himself heard and understood in speaking is very great, and the exertion quickly fatigues him, so much in fact that the distinct enunciation of a series of words is

impossible; coughs a little in the morning; though he has had for years bad hearing, deafness appears to have augmented since the blow.

Larynx.—Examination with small mirror shows an orifice now tolerably patulous; vocal cords very slightly congested; no swelling of consequence in any part of the organ; left vocal cord approximates, though in a very slight degree, towards the middle line in the effort of phonation.

Treatment.—Paralization of cords: strychnie sulphatis gr. 1-30 ter in die sumend.

Remarks.—There are few facts more familiar to the general surgeon than localized loss of function, in cases of contusion, compression, or laceration of nerves. Such loss manifests itself often in the upper or lower limbs, and less frequently in some portion of the head or trunk. A lesion, similar to the one of which we have just given the history, is very rarely reported, we do not say encountered, because such cases must, it seems to us, oftentimes occur, and when the force of the blow is sufficient, we should presume that loss of function, temporary or permanent, would be almost of necessity the consequence. After considerable research in the works of authors who are recognized authorities on injuries of this nature, and in the periodical medical literature of the day, we have been able to lay our hands on but one analogous case. The history of it may be found in some very interesting lectures on the Principles of Surgical Diagnosis by Le Gros Clark, published in London, 1870, pp. 228, 229; but in this case, though "complete aphonia" is mentioned as being a prominent symptom, no laryngoscopic examination was made, nor was the internal condition of the vocal organ even conjectured. We have found, it is true, a citation of one other "illustrative history of a blow on the neck" in Dr. Weir Mitchell's recent and admirable work on Injuries of Nerves and their Consequences.

Reference is there made (p. 96) to the Sanitary Commission Medical Reports for 1867. On consulting this memoir (p. 418), we have not found aphonia, dysphagia, or dyspnea noted among the symptoms which followed the blow. There was local swelling over the contused region, and, Dr. Mitchell adds, "also a good deal of pain in the right arm for a few minutes, owing, as I supposed, to violence done to the brachial plexus. . . . slight pain was felt in the forearm and hand at intervals until the twelfth week." Now in the case which we report, no pain in the arm, forearm, or hand has thus far been felt, and there is therefore no reason to believe that the brachial plexus was contused or otherwise injured by the blow.

In a general way, and with our actual knowledge of the physiological functions of cranial nerves, and having regard to the symptoms above noted, we might fairly infer that the spinal accessory, glosso-pharyngeal, and more apparently perhaps the vagi, which send sensor and motor branches to the intrinsic muscles and mucous covering of the larynx, had been disturbed in their governing power.

But how would it have been practicable without the intelligent use of the laryngoscope to see, recognize, and therefore be able to affirm positively that the left vocal cord is the seat of the trouble which causes loss of voice,—when there is organic lesion of the left recurrent nerve, or loss of its healthy power of innervation.

Accuracy of diagnosis is in this instance of essential importance, for without it the treatment would evidently be uncertain—perhaps injudicious or injurious. A circumstance in our case needs explanation: it may be asked in what manner a blow on the right side of

the neck can produce paralysis of the left vocal cord.

Our anatomical knowledge furnishes us the answer. The right recurrent nerve is situated between the right border of the trachea and the bodies of the cervical vertebrae. Evidently the impulsion of a blow from right to left would tend to force the trachea out of the way of the recurrent nerve on the right side, and unless the full force of the blow should impinge immediately on *this* nerve (which is almost impossible), no injury would be done it.

The left recurrent nerve is also deeply situated among the soft tissues of the neck, and it lies in a sort of furrow, or angle, formed by the contiguous relations of the trachea with the œsophagus. We can on this account appreciate the compressing or lacerating effect of the trachea and larynx being rapidly and violently forced into rude contact with the protecting sheath which surrounds its delicate fibres. Such, then, is our explanation of the pathogeny of the lesion of the left recurrent nerve, which holds under its sway, as we are all aware, the mobility of the left vocal cord.

With regard to the *dysphagia*, so prominent a symptom during many days, we believe it may be satisfactorily accounted for by the almost direct contusion of the pharyngeal plexus which governs, as it were, our power of normal deglutition.

Most probably the branches of the spinal accessory which animate the glosso-pharyngeal muscles and some bundles of fibres of the superior constrictor muscle, were contused, and thus the naso-pharyngeal cavity during deglutition was not closed so imperiously as it is in health.

The very fact that our patient during many days was obliged to pinch his nose in order to accomplish deglutition properly, would point to the plausibility of this explanation, and substantiates in our mind the reality of temporary paralysis of the soft palate. In a somewhat similar way a solution may be, we believe, offered of the paroxysms of cough.

The natural explanation is (as far as it goes), that particles of food, which in vulgar parlance "passed the wrong way," penetrated into the larynx whilst the patient was swallowing, and were the cause of these attacks.

But why did they enter the larynx? It may be said that owing to the concussion caused by the blow, the function of the epiglottis was interfered with, and this organ did not close the upper orifice of the larynx in that perfect way according to which this natural valve was intended to perform its proper function.

But let us remember that the action of the epiglottis is purely passive and mechanical. No muscle exerts its contractility in order to bend it down. In the movement of deglutition the larynx is drawn upwards and forwards, and at the same time the tongue is retracted, as it were, at its base, and helps in a great measure to press the epiglottis over the laryngeal opening. If, however, the glosso-pharyngeal nerve had been contused in many of its fibres (and we are now having in view the motor ones, which come to it directly from the spinal accessory), why then the sluggishness of the tongue to perform its rôle properly, is readily interpreted and the cough explained.

The *dyspnoea* which was so distressing at first, and which even now is occasionally a source of anxiety, may be attributed, without effort of the imagination, to perturbation of the trunk of one or both pneumogastric nerves. The delicate muscular fibres which encompass the smaller divisions of the bronchi have been, without much cause for doubt, partially paralyzed, and when they have been, and are, called upon

to perform some extra work, during rapid or excessive breathing, they become readily fatigued. The local congestion and swelling, and the complete paralysis of the left vocal cord, which tended to narrow and diminish the normal calibre of the larynx, would explain this dyspnoea sufficiently well, but for its continuance (though not showing itself at all times), with a tolerably patulous larynx. In the case reported by Clark, among other symptoms, noted "manipulation of the larynx caused aphonia, and so likewise did the effort of deglutition; aphonia was complete," but there was no choking or cough after deglutition, and no mention is made of symptoms of difficult breathing. In neither his case nor ours could any irregularity be detected when the thyroid cartilage was examined.

Crepitus, abnormal motion, intense and very limited pain or pressure, or displacement of organ, were at no period perceptible to the senses.

The reddened sputa expectorated in moderate quantities for some hours after the assault, furnish the only reason for supposing that there may have been a fracture of the hyoid bone or laryngeal cartilages. Most probably, the slight sanguineous expectoration was due to tearing of mucous membrane, or else there was laceration of, or some extravasation from, the capillaries of the interior lining membrane. Finally, we would draw attention to the fact, that the impaired audition of our patient was aggravated by the blow.

All medical men are familiar with the cough produced by introducing an ear speculum, probe, or other foreign body into the external auditory canal. This physiological phenomenon is explained by reflex action of the vagus, inasmuch as one of its sensor branches (auricular), first described by Arnold, takes origin in the superior cervical ganglion, and sends two very small divisions to the *meatus auditorius*.

Most authors apparently ignore the existence of a third division of the auricular nerve, which is distributed to the *membrana tympani*. A description of its course may be read in the remarkable treatise of anatomy by Sappey (Paris, 1852, vol. 2, p. 287). In the case we report, perturbed innervation of this branch of the vagus has evidently been one among many sequelæ, of a blow on the neck.

The prognosis of our case must, of course, depend upon the more or less nerve-trouble existing.

Have we had mere compression of the left recurrent nerve, or is laceration of some or many fibres to be considered probable?

Has there been considerable effusion of blood and plastic lymph at the time of the accident, interposing itself in the connective tissue between the nerve-fibres? Are we in danger of chronic neuritis of the left recurrent nerve, or of actual or future degeneration of the muscular tissue incorporated in the calibre of the left vocal cord?

All these questions are very difficult to answer.

In the case already quoted more than once, the patient recovered rapidly. "In about ten days she began to recover her voice; and in three weeks was quite well."

Our patient has not progressed so favorably. More than two months have elapsed since the night on which the blow was received, and he yet speaks in a low, husky, imperfect manner. Inasmuch, however, as he has improved somewhat, though slowly, as the other symptoms, so severe at first, have entirely disappeared (*dyspnoea* excepted), and as the general health is good, we think the prognosis should be hopeful—in the sense of ultimate recovery.

Knowing, however, the snail's pace with which the effects disappear of even less serious nerve-lesion than

is here evidently present, we doubt very much whether we ought to look with confidence to a speedy cure.

Our intention is to begin by prescribing small doses of strychnine internally, and, to aid the action of this powerful nerve-tonic, with local applications of faradic electricity, made frequently and directly to the affected cord, by means of Mackenzie's electrode.

This method of treatment, we may add, would have been commenced ere now, had the patient been more regular in his attendance at the Dispensary.

ROOSEVELT HOSPITAL.

REPORTS OF PRACTICE AND PECULIARITIES OF TREATMENT.

(DR. LA GRAVE, HOUSE-SURGEON.)

GONORRHEEA.

INJECTIONS of the silicate of soda have been employed in the treatment of this affection in both acute and chronic stages.

R. Silicate of soda..... grs. xx.
Aque..... ʒ viii.
M.

The injections were given three times a day. So far as employed, the results obtained were eminently satisfactory. No other treatment was combined with it.

ASPIRATION OF THE BLADDER.

The case was one of urethral fever following the introduction of instruments for the relief of stricture. The fever and general constitutional disturbance was so intense that it became necessary to adopt some means of relieving the bladder of urine other than the introduction of a catheter. Resort was had to the aspirator, and the bladder was emptied some four or five times by the introduction of one of the needles above the pubes. By the operation the urethra was placed perfectly at rest, and the fever soon subsided.

Another case was mentioned in which it became necessary to evacuate the bladder in some manner other than through the natural channel. The aspirator was used three or four times for that purpose. Operation, supra-pubic. The patient soon after died of the disease with which he was afflicted. At post-mortem, it was very difficult to recognize the point of puncture upon the inner surface of the bladder made by the needle, and not the slightest traces of ill-effects could anywhere be found.

ULCERS.

This class of cases, "old ulcers," are quite uniformly dressed with Labarraque's solution (liq. sodæ chlorinatæ) until the sore becomes surgically clean. The solution is to be diluted with water, according to circumstances. If then the granulations have a healthy appearance, the ulcer is strapped, and the limb bandaged. If the granulations become flabby and inactive, a dressing of balsam of Peru is applied, and over that straps and bandage. Grafting is resorted to in certain cases, when the ulcer is of some size, and, in this manner, a certain proportion are made to heal very rapidly.

BUBOES.

The treatment adopted in these cases varies somewhat from that in general use. When one of these glandular enlargements presents itself, when the skin is thin, of a bluish color, and deeply undermined, the

entire covering of the excavation is removed by the knife, affected glands swept away, and then it is treated as an open ulcer.

A case was seen which well illustrated the results obtained by improper management of these enlargements. The case was one of ordinary suppurating bubo. It had evidently been opened by simply plunging a lancet into it perpendicularly. Discharge of pus was apparently free, but upon examination, when the case was admitted, it was found that the pus had burrowed among the tissues until the abscess extended down upon the thigh. The anterior walls of the excavation were entirely removed. The now open ulcer was being treated with carbolized water, one part to twenty, filling the cavity with scraped lint wet in the solution, covering this with sheet lint wet in carbolized oil, one part to twelve, and over the whole a piece of oil silk. The granulating surface presented a clean and healthy appearance, and was healing quite rapidly.

BURNS.

For this class of difficulties white-lead paint seems, to meet the indications of treatment as satisfactorily as any material which has been employed. This is interesting, from the fact that almost every plan of treatment which has ever been devised has been employed, and the leaning is towards the paint dressing. Mix as for painting, except considerably thicker, and apply with a brush. It is much more *cleanly* than Buck's burn mixture or Carron oil, and that is not an unimportant element in its favor. A very neat and satisfactory dressing for superficial burns consists in coating the surface with mucilage, and then covering it with powdered Lycopodium.

TRAUMATIC PNEUMO-HYDRO-PERICARDIUM.

The young man had received a stab in the pericardial region, which had penetrated the thoracic walls and entered the pericardium.

Pneumo-hydro-pericardium was soon developed.

At present he is well on the way towards recovery. The fluid has been almost entirely removed. There was remaining a loud friction sound, heard with greatest intensity to the right of the sternum. The heart was displaced towards the right. The constitutional disturbance throughout the entire progress of the case had been very slight indeed.

Pulse, temperature, and respiration had scarcely been disturbed. It was only by means of physical signs that the presence of the pericardial difficulty was recognized, and its daily changes noted. Absolute quiet in bed has been rigorously enforced, and only a trifling amount of medicine administered. The infus. of digitalis was at one time administered in drachm doses three or four times a day, and small doses of opium were added to give a little additional quieting effect. He will probably recover, if meddling interference is avoided.

FRACTURE OF THIGH.

The best results in regard to shortening are obtained by the following treatment. If no swelling is present, place the limb at once in plaster-of-Paris splint reaching above the ilium. If swelling is present, apply Bück's extension until it has nearly or quite subsided, and then apply the permanent dressing. About the time union is to commence, if the dressing is somewhat loose, it is removed and a new splint applied. The results are very flattering.

UNUNITED FRACTURE OF HUMERUS.

The success attending the treatment of this case was at the least interesting, for *failure* had been the characteristic feature. The man was somewhat beyond the middle period of life, and of good constitutional tendencies. During the progress of the case thorough manipulation, rubbing the ends of the fragments together, had been resorted to, but without success. The extremities of the fragments had been exposed, sawed off, and wired together, but union was not secured. Necrosed portions of bone had been removed, and were followed by extra treatment for the purpose of exciting inflammatory action sufficient to cause union, but every measure adopted had failed. The limb was useless. Amputation was desired, and the operation was performed. The extremities of the fragments were found smooth and eburnated.

BELLEVUE HOSPITAL.

(DR. PERRIBERRY, HOUSE-SURGEON.)

FRACTURE-BED.

It was noticed that all the patients whom it was necessary to confine in bed during the progress of the treatment of fractures, were placed upon what was called the fracture-bed.

These beds are arranged in the following manner: take a couple of boards of the ordinary length for a bedstead, and sufficiently wide to give the width of an ordinary single bed, and fasten them with nails to the edges of two pieces of board about ten or twelve inches wide, and long enough to match the width of the bed. These cross-boards are fastened at a distance from each other corresponding to the inside measurement from head to foot piece of the bedstead, and form supports for the boards above. Braces extend from the lower edges of the cross-boards, or legs of the bench, to the centre of the boards upon which the patient is to lie. These are for the purpose of preventing too much spring. This bench-like bedstead is placed upon a bedstead of ordinary height, and upon this is placed a soft mattress. This arrangement elevates the patient in such a manner that the necessary dressings can be much more easily applied than upon an ordinary bed, and furnishes practically an unyielding surface.

A man fifty-seven years of age, with intra-capsular fracture of the neck of the femur, was placed upon one of these beds, and a long, lateral splint was applied while we were present.

The splint, extending nearly to the axilla, was fastened to the side of the body in the thoracic region by means of a band five or six inches in width, passing around the body, and secured by tabs or by stitching it to the covering of the splint. In order to prevent this band from becoming gathered up into a rope, a light piece of wood, as long as the band was wide, was quilted into the band near its extremities.

If necessary, like pieces may be quilted-in in other places, and in such manner as not to subject the tissues to undue pressure when the band is adjusted.

MORBUS COXARIS.

A male patient, past the middle period of life, had received an injury to his hip seven weeks previous.

Symptoms of hip-joint disease had developed. The patient was placed upon one of these fracture-beds, a moderate amount of extension applied and maintained, and he was feeling exceedingly comfortable.

UNUNITED FRACTURE OF THIGH.

An old lady had suffered from fracture of almost all the bones of her body, which were generally very fragile. Her femur upon the right side was now in an ununited condition, and it was expected that it would remain so permanently.

METALLIC STRIPS.

These little accessories in the application of plaster-of-Paris splints are regarded as being very valuable, and would commonly be employed if they could be obtained. They give strength to the splint without materially increasing its weight. Their application precludes the necessity of keeping up manual extension until the splint has set. They may be so adjusted that fenestra can be made in the splints, which will embrace a goodly share of their circumference without endangering the efficiency of the apparatus for purposes of retention. By means of these strips starch, dextrine, or other slow-drying material can be much more advantageously employed than in the ordinary manner.

BOOK-SPLINT.

The case was one of fractured leg. The splint (plaster-of-Paris) had been so adjusted that it was flexible behind, and when opened in front it was like opening a book.

The splint was applied in this manner: only sufficient number of roller bandages, covered with plaster, were employed to insure retention, and yet give sufficient flexibility behind to permit the splint to bend, and not break. Two rollers are usually sufficient. The sides of the splint are made unyielding by the addition of strips of blanket saturated with plaster mixture, or by the addition of metallic strips. The splint, when dry, can be easily cut through in front, and can then be removed, and readjusted to suit the wishes of the surgeon. It is secured in position by an external roller bandage. In certain cases this apparatus may be very useful.

Progress of Medical Science.

SULPHUR IN THE TREATMENT OF ACNE.—Dr. Sidney Ringer says (*The Lancet*, Feb. 21): "The topical effects of sulphur ointment, or, of an iodide of the hypochlorite of sulphur, or, still better, of the iodide of sulphur of the Pharmacopœia, is most marked on *acne indurata* and *acne rosacea*, these effects being twofold, and even opposite, according to the stage of the eruption. If applied at the very commencement of the eruption, as soon as the little hard knot is felt under the skin, further development is arrested, and the hardness speedily disappears. For instance, if smeared over the hardness just before going to bed, in the morning scarcely

any induration will be felt, though after a time, perhaps, from exercise or the irritation from washing, much of the hardness may return, to be again removed by a new application of the ointment, so that in two or three days a papule that threatened to become of considerable size may be completely dispersed.

When, however, the nodule has advanced further, and suppuration has set in, then the effects of the ointment are much like those of the sulphides, administered internally, on boils, hastening maturation, limiting the swelling and hardness, and thus considerably curtailing the duration of the eruption. Nay, further, if rubbed over the skin, it appears to check the formation of acne spots. If rubbed over the nose and neighboring parts of the face in acne rosacea its effects are often most striking. Not only does it act as an acne indurata, but the hardened, swollen tissues become softened and reduced to a more natural state. He has found the iodide of sulphur likewise useful in bromic acne, reducing the eruption, or at least considerably reducing the size of each spot. In acne the ointment should be thinly spread over the eruption, night and morning.

ON SULPHIDE OF POTASSIUM, SULPHIDE OF SODIUM, AND SULPHIDE OF CALCIUM.—Dr. Sidney Ringer speaks enthusiastically of the influence of these remedies upon the suppurative processes, such as abscesses, boils, and serofulous sores. When sulphide of calcium or potassium is administered, a thin, watery, unhealthy discharge becomes at first more abundant, afterwards diminishing, and throughout continues thicker and healthier, possessing, indeed, the characters of "laudable" pus. The condition of the sore improves correspondingly and its healing is promoted. The sulphides appear, often, to arrest suppuration, serving to reduce inflammation, and avert the formation of pus.

The effects of these remedies are equally conspicuous in mammary abscesses, although in rare instances they appear temporarily to increase the pain—a remark which seems, sometimes, to hold good with respect to boils. But, as a rule, the pain is speedily mitigated. Singular to say, he has found these remedies of much less use in forwarding the maturation and expulsion of pus in indolent tumors. For the relief of boils and carbuncles, the tenth of a grain of sulphide of calcium, given every two hours, generally prevents the formation of fresh boils, while it lessens the inflammation and reduces the area of existing boils, and quickly liquefies the "core," so that its separation is much more speedy than usual. In some cases of deep-seated boils and abscesses of diabetes they are powerless.

A very beneficial effect appears to be exercised upon suppurating serofulous glands in the neck. Here again they hasten the elimination of the pus, and subsequently the cheesy, serofulous matter.

RESECTIONS OF JOINTS DURING THE FRANCO-GERMAN CAMPAIGN.—In the report of the surgical treatment and results of gunshot wounds in the 14th Army Corps of the German army, Dr. Beck, Surgeon-General, has furnished many valuable statistics, and drawn from them much sound and practical teaching. In reference to the resection of joints, he attaches much importance to the method of operating, regarding a good result as in a great measure attributable to compliance with certain fixed rules. He believes it essential that the wounds should not be large, the adjoining tissues should not be lacerated, as few vessels as

possible interfered with, and the diseased portions of bone denuded of the periosteum. In operating on the elbow and knee-joint he makes the H incision, at the wrist and ankle-joint two long incisions, and at the shoulder and hip-joint a single long incision. The preservation of periosteum is advocated on the ground that it protects the exposed surfaces of the bones from the purulent infection of the secretions in the wound, and not from the fact that it promotes the growth of new bone (which, in fact, it often fails to do). Finally, he lays great stress on a judicious after-treatment, which may, in some cases, require but a few weeks, but in others be protracted to one or more years.

The following are the results which he has tabulated: there were two resections each of the finger and metacarpal joints, and one of the wrist, all of which were successful. Of seventeen resections of the elbow-joint, only two died. Of these fourteen were classed as primary, with one death; one intermediate and two secondary, with one death, owing to repeated hemorrhages. One of these patients submitted to an amputation, but recovered. It is interesting to observe that in those operated on by the H incision the results were uniformly good; while, on the other hand, when the long incision was made, pyæmia occurred twice and secondary hemorrhage twice. Another important point to be remembered is, that the limb should be kept well supported, and very early passive movements should be avoided. In these cases the final results, so far as they could be ascertained, were satisfactory. Of eighteen resections of the shoulder-joint, eight died; of these eight were primary operations, of which three died; one was intermediate, and died; nine were secondary, of whom four died. In the three cases of primary operation, two had extensive lacerations of the shoulder-blade, from wounds by shells, and all three had symptoms of septicæmia. The operations were done some sixty hours after the receipt of the wounds. In the case of the intermediate operation the patient had been abandoned by the surgeon, and was found in the most deplorable condition. Of the secondary resections, three had pyæmia at the time of operation. The author never removed more than three inches of bone, and was always careful to secure a free exit for the discharge at the lower portion of the wound. The final results in these cases were uniformly good.

Of seven resections of the ankle-joint, all recovered satisfactorily. Of the resections of the knee-joint, of which five were primary and two were secondary, seven died. The two that survived were primary operations; one of them, however, suffered amputation subsequently, but the other had a pretty useful limb. The causes of death were pyæmia in almost all the cases. The author regards this operation at the knee-joint as unjustifiable in military surgery, except under the most favoring circumstances.

Five resections of the hip-joint were performed; four of these were secondary and one primary. A single one of the secondary survived, all the others terminated fatally. The hopes that had been entertained of this latter operation were not sustained by the experience of the campaign; and the author's views were so far modified by the results, that he would advise, in cases that are seen early, the removal only of loose fragments of bone, and possibly cleansing of the wound. Operative measures should certainly be postponed until the expectative treatment has been thoroughly tried. To promote a free discharge from the wound, a drainage-tube is advised.—*Schmidt's Jahrb.*, 11, 1873.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, May 1, 1874.

LUNACY COMMISSIONERS.

MR. PAYNE's bill for the appointment of Lunacy Commissioners has again brought to notice the question regarding the best method of procedure in the case of persons supposed to be insane and proper subjects for asylum care and treatment. The bill provides in effect that instead of the two respectable physicians who now make the diagnosis and affidavits on which Lunacy commitments are based, certain physicians, styled Commissioners of Lunacy, shall perform these functions instead. As this question has thus again been raised, it is not improper that it should be again discussed.

The grounds on which the necessity for a change in the law is predicated are the fact that sane persons are supposed by many to be oftentimes confined in Asylums for the Insane, knowingly and with evil intent; the fact that some persons have been thus confined at least unwittingly; and the fact that oftentimes the Judge who makes the commitment does not have the means of knowing whether the examining physicians are *respectable* or not. The object of the law is the avoidance of these real or supposed evils by the appointment of examining physicians whose known integrity and whose high official position shall insure public confidence; whose experience and ability in the diagnosis of insanity shall prevent mistakes; and whose official status shall assure the Judge of their respectability.

It is possible and even probable that mistakes in diagnosis are sometimes made by physicians regarding the mental condition of certain persons. Experts in insanity sometimes differ in their views. How much more likely, then, it is that physicians of little experience in the diagnosis of mental diseases should sometimes make mistakes. Physicians also differ regarding the diagnosis of other diseases; and in such cases one party must be in the wrong. They are at least as

liable to err in the diagnosis of mental diseases. As a matter of fact the commitment of sane persons to Lunatic Asylums is a rare occurrence.

But the assumption that physicians, knowingly and with evil intent, assist in procuring the commitment of sane persons to Asylums for the Insane is entirely gratuitous. The proofs of such a misdemeanor have never been adduced; and the assumption that physicians commit perjury for the sake of depriving a fellow citizen of his liberty is too monstrous for belief, without the support of positive proofs.

If the Lunacy Commissioners who might be appointed under the proposed law were really experts in insanity, it is reasonable to suppose that the number of mistakes in diagnosis would be diminished. There are other considerations, however, that are worthy of serious attention. The proposed measure would assuredly diminish the interest taken by physicians in the observation and study of such cases of insanity as came under their notice; and this would be greatly to the disadvantage both of the community and of those who make a special study of the subject.

The general practitioner of medicine has especial opportunities for observing the earliest manifestations of the disease. Not only this, but he is oftentimes acquainted with the personal history and characteristics, not only of the patient, but of all his immediate relatives. Thus he has opportunities for learning the physical, the moral and the hereditary causes of insanity. These opportunities he will improve if he have a personal interest in the subject; otherwise not. He may be of the greatest aid to those who make a special study of the subject of insanity and his active co-operation should by all means be secured.

As cases of insanity come first under the observation of the general practitioner, he should be prepared to give such advice and immediate treatment as may be required. Insanity is a disease that, in some cases at least, may be treated at home. In all cases advice is needed during the earliest stages, and before the patient can be removed to an asylum. The general practitioner should be taught that he has a responsibility in the management of these cases, instead of being made to feel that insanity is a disease with which he has no concern.

There is a still more important reason why general practitioners of medicine should be personally interested in the study of insanity and of its causes; that is, the prophylaxis of the disease. There can be no doubt that many cases of insanity might be prevented, especially in the young, if such advice regarding physical and mental hygiene were given as lies within the province of the family physician.

There is a feature, however, in the existing method for committing insane persons to asylums which would seem to be susceptible of improvement. The affidavits of two physicians are required by law. It is undoubtedly the general fact, that the family physician, or the

practitioner who first sees the patient, takes the principal part in the investigation and in the decision on the case. Whenever a second physician is called in for advice in the case of other diseases, it is usually thought desirable to secure the services of some one who has had greater experience in the particular disease in question than the family practitioner. It is thought desirable that the *consulting* physician should be specially skilled. In like manner it seems desirable, that the second, the *consulting* physician, who is to assist in deciding the important question regarding the existence of insanity and the necessity of sequestration, if insanity do exist, should be one who is specially skilled in the diagnosis of mental diseases. If this method were habitually pursued, the general practitioner would be aided, instructed, and stimulated to a further study of the subject; the observations already made by the general practitioner would be utilized, especially if all ascertained facts bearing on the case were required to be written down and transmitted to those to whose care the patient might be entrusted; the best advice attainable would be secured regarding the management and disposition of the case; mistakes in diagnosis would sometimes be avoided, and the public would be reassured.

If it were the practice to call in the best attainable talent in consultation, it would be of little importance whether the consulting physician were appointed by law or not, since the main object would be obtained. There are, however, certain duties and powers that should be defined and established by law. The affidavit of the fact of insanity should be required to be made within a specified time after the patient has been visited and the diagnosis made; a statement of the facts on which the diagnosis was founded should be written out and included in the affidavit; a separate statement being made of those facts which were observed, and of those which were obtained on the testimony of others, and there should be the power of compelling the attendance of witnesses and of examining them under oath. This last provision is required in order to insure a full understanding of certain difficult cases; and for the reason that such important decisions should not be influenced by the unsworn statements of persons who may have strong inducements to misstate the facts.

In fine, the points sought to be established are that the general practitioner should have the same duties and responsibilities as at present in the diagnosis of insanity, and in securing the sequestration of the insane; that he should be assisted by an expert in the diagnosis of mental diseases; and that certain powers should be conferred and duties enjoined by law in order to insure a proper statement of the facts, and in order that all the facts bearing on the case may be transmitted to the institution where the patient is to be treated.

AMERICAN MEDICAL ASSOCIATION.—The next meeting is to be held at Detroit, June 2, 1874.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 5, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

USES OF BROMINE AND ITS COMPOUNDS.

THE paper for the evening was read by Prof. Lewis Smith upon the "Therapeutical Uses of Bromine and its Compounds."

The paper was more particularly devoted to the consideration of Bromide of Potassium, and also almost entirely restricted to the therapeutical uses of this remedy in the treatment of diseases of children.

When a new remedy of real value is brought before the profession, as a general rule too much is claimed for it, there is a tendency to give an undue prominence to a new therapeutical agent, and some time usually elapses before it assumes its proper level, and its actual value becomes definitely determined. With regard to the bromide of potassium, it is probably as safe a remedy as can be found in the Pharmacopœia. With the exception of two conditions, namely, an irritable state of gastro-intestinal mucous membrane and organic disease of the kidney, no deleterious results will, as a rule, attend its administration. In children, this remedy may produce injurious results, if administered when the condition of kidney is present which follows scarlet fever, and its use, therefore, is to be recommended with great caution, if not entirely discarded.

The injurious results sometimes attained from a long continuation of the remedy, such as the formation of carbuncular and cutaneous eruptions, are, for the most part, temporary. The impairment of the mental faculties which is sometimes seen, was considered as perhaps being due to an anæmic condition of the nervous centres.

Loss of memory, imbecility, dimness of vision, irregular gait, etc., may be produced by large doses, or long-continued use of the remedy, but, as a rule, these effects disappear with its discontinuance.

Small doses sometimes produce marked effects which are apparently of a serious nature, but soon pass away.

Some remarks were made at this point relative to the elimination of bromine as a result of decomposition which the remedy undergoes in the stomach and intestines. The conclusion arrived at was that bromine was not eliminated in the breath or otherwise, unless the remedy met with some *unusual* compounds in the system. Combination of the remedy with an alkali, such as bicarbonate of potash, will prevent this elimination, if there is suspected danger. The remedy had been employed in the following diseases with a marked degree of success:—

CONVULSIONS OF NEW-BORN INFANTS.

Three cases were mentioned belonging to this class. In the first case, $\frac{1}{4}$ gr. doses of the remedy were administered every two hours. Recovery. In the second case, two grains were given every three hours. Recovery. In the third case $\frac{1}{2}$ of a grain was given every three hours. Recovery.

In cases of *trismus nascentium* the bromide is much inferior to hydrate of chloral, for occasionally a case of this affection recovers under the influence of chloral, but the bromide of potassium is of no special service.

DENTAL IRRITATION.

The remedy, in this class of cases, is so salutary in its effects, that the gum-lancet need scarcely ever be

resorted to. It is to be administered in doses proportionate to the age of the child, and repeated according to circumstances. The remedy is of service in the treatment of all local diseases except gastro-intestinal irritation and renal disease, where convulsions are threatening.

BRONCHITIS AND PNEUMONIA.

The remedy is serviceable, therefore, in the treatment of cases of bronchitis or pneumonia where eclampsia has already been developed or is imminent. It not unfrequently happens, especially in children, that a convulsion or convulsions mark the accession of these affections, and under such circumstances the bromide of potassium will, in most instances, produce very beneficial effects.

PERTUSSIS.

The eclampsia sometimes developed in the disease as the result of reflex action from general constitutional disturbance, can ordinarily be relieved by the use of this remedy.

ERUPTIVE DISEASES.

In certain cases belonging to this class, where symptoms of great nervous agitation and irritation are developed, much benefit may be derived from the use of bromide of potassium. If it is feared that its sedative effects may become too great, stimulants may be administered in combination. In general, however, the remedy would not be continued for any considerable length of time in this class of diseases, on account of the undesirable depressing effects which might be produced.

ONANISM AND SPERMATORRHEA—MENINGITIS.

In the initial stage of this disease, before the meningeal exudation has taken place, bromide of potassium is to be regarded as being a more serviceable remedy than iodide of potassium, the remedy which has been so long employed. It has to a very great extent superseded the iodide. It is in this initial stage of the disease, however, that the most marked benefit is to be derived from its administration.

EPILEPSY.

His experience in the use of bromide of potassium in the treatment of this disease had not been very extended, but the opinion expressed was to the effect that the remedy would prove most efficient when commenced in the earlier stages of the disease.

In the discussion which followed the reading of the paper,

Dr. SQUIBB remarked as follows: It is well worth knowing that bromide of potassium, and indeed sodium and ammonium, are all of an unusual degree of purity, as found in the market, for medicinal substances which are manufactured in so large quantities. There is no material impurity found in these articles which will detract from their therapeutical usefulness. With regard to the subject of decomposition of the bromides in the *prima vie*, the most common source of decomposition is not the presence of other bases, but the presence of *stronger acids*.

He had read of several instances where bromine had been detected in the breath and bromide of potassium in the urine, but it is altogether probable, however, that such cases are very rare. In general, the condition of the secretions is such as to protect the bromide of potassium or any of the compounds of bromine against any decomposition.

Epilepsy was the only disease in which he had had

any personal experience in the use of bromide of potassium.

The history of five cases was then related, all of which were permanent in character, and had been of long duration, when the treatment by bromide of potassium under his direction was commenced. The point which he desired to make with regard to the treatment of epilepsy with this remedy was, that physicians often fail in giving patients benefits which they otherwise might receive on account of the lack of quantity administered.

In the first case, the history of which he related, it required some months to reach the doses which were necessary to arrest or materially modify the occurrence of the paroxysms; and no success was obtained in that direction until doses of from 32 to 35 grs. t. i. d. were administered. When these doses were reached the paroxysms were apparently influenced by the remedy, although not arrested.

Bromism is always to be sought before the efficacy of the remedy can fairly be said to be tested. *Bromism* varies. In one instance a sensation of sleepiness or heblitude will be produced. The patient will, perhaps, while engaged in his work, writing or whatever it may be, perform the movements of the hand, etc., somewhat slower: this will gradually increase until he finds himself borne down with a heaviness which gives an irresistible, or almost irresistible, tendency to sleep and stupor. The development of these symptoms has been so closely observed by many patients that they have been cognizant of the fact that their pen was moving slower and slower, until at last they drop off into a drowse of a few seconds' duration, and then awaken, finding the point of the pen upon the very letter where it was placed before the occurrence of the momentary loss of consciousness. These are among the earliest symptoms, and will vary in degree, still gradually increasing until other effects are developed, such as irritability of temper and mental disturbances, varying according to the circumstances and peculiarities attending each case.

To reach bromism required different doses in every case which he had observed. In one case of an inveterate nature, one which had been under previous treatment, and in whom the paroxysms were of frequent and very regular occurrence, no effect whatever was produced short of 45 grs. t. i. d.; and the maximum effect of the remedy was not reached short of 60 grs. t. i. d., continued for 10 or 15 days. Bromism occurred, but without positive arrest of the paroxysms.

When bromism has been produced an intermission in the use of the remedy can be safely permitted without lessening its effect. At the end of about ten days it should be resumed in the *maximum doses at which it was discontinued*. When bromism occurs again, the remedy should be discontinued for a short time, and then renewed, and so on. In this manner the remedy can be continued certainly for two years and a half or more without detriment.

The third case related was one in which the patient, 22 years of age, had been habitually epileptic for many years. The imbecility which had been developed seemed to be approaching idiocy. He had lost the power to either read or write, and, in brief, was in a most deplorable condition. He was also the subject of gout.

He had already been under treatment by the use of bromide of potassium, but the doses were immediately increased from 15 grs. to 35 and 40 grs. t. i. d. Very soon the paroxysms began to abate. The case illustrated another important element in the treatment of epilepsy, and that was the element of time. Good re-

sults in many cases are *not* obtained speedily, and could only be obtained by steady perseverance until bromism had been produced, and then going back of this a little, continue the remedy for a long time. After about three years of treatment in this case the disposition to the occurrence of the paroxysms seemed to pass away, and he began to recover his mental power. Since that time he has made marked improvement, and now reads and writes nearly as well as he did before the occurrence of the epilepsy. Still the doctor did not regard either of these cases as being cured. Occasional paroxysms have occurred, although, each time, they were in obedience to some good and well recognized cause.

In the fourth case, the paroxysms occurred exclusively at night, and once a month. They were so violent that the man's shoulder was dislocated at several different times. He had been taking bromide of potassium for one year before he came under his observation. He was then advised to take 40 grs. t. i. d., and that dose was increased by 5 or 10 grs. before any effect was produced. When the desired effect of the remedy had been produced, it was continued for three or four months only, before the paroxysms were entirely suspended. In this case there was developed a peculiar kind of bromism. The patient would detect the approach of the condition by the fact that his pen, as he was writing, would begin to move slower and slower, and, if he continued writing, he would momentarily fall asleep. This man also had a staggering gait, it being the only case in which this symptom was developed. There was also some tendency to fall forward when walking.

When these symptoms were developed, the remedy was omitted for a time, and the symptoms would pass away. The remedy would then be commenced at the maximum dose, and continued until bromism was again produced. The remedy was continued in this manner, and the patient was finally free from paroxysms *for one year and a half*. The medicine was then discontinued, *but the paroxysms returned*. The patient again came under treatment, and the bromide of sodium was substituted for the bromide of potassium on account of the peculiar effect which the latter salt has upon the muscular system. He was soon free from paroxysms. A later attack and suspension of paroxysms took place, and then the patient passed beyond his observation.

The last case was in a girl, 13 years of age. She had been under treatment with bromide of potassium. The doses were increased to the production of bromism, and she had not had a paroxysm since Aug. 1873.

He did not regard any of the cases as absolutely cured and was of the opinion that *habitu* had very much to do with recurrence of the attack. In people who are otherwise healthy, *habitu* confirms, strengthens and increases the paroxysms. A long time is necessary in order to break up the disposition.

The points of importance with regard to treatment which he wished to impress were that want of success very frequently followed from insufficiency of dose, and the inefficiency with which the case is dogged out, pursued and adhered to, until it gives away.

MODE OF ADMINISTRATION.

He always employs a watery solution of the strength of 12½ grains to the fluid drachm. The solution is always filtered, for by this precaution a solution which will remain clear is obtained.

The best vehicle for the administration of the remedy is ice-cold water. He has not found any stomach which has rejected the remedy when given in this manner. It is not well to administer it too near the

digestive process. It should not be administered nearer than fifteen minutes before a meal. If given immediately before a meal, there will probably be developed evidences of interference with digestion. This is a rule which, for obvious reasons, it is well to observe, with regard to the administration of any of the alkaline salts.

ITS ACTION ON THE CAPILLARIES OF THE BRAIN.

Dr. CARO remarked that it was altogether probable that the bromide of potassium has been used in past years as a kind of fashionable remedy, and, perhaps, many times without very definite knowledge why it was used. At the present time, however, we have arrived at a better knowledge, and the remedy can be prescribed with a degree of certainty that we are to obtain such and such results.

The remedy is now recognized by the profession in general as being one of efficacy, and if the results obtained, when it is administered, are not what were expected, it may be from want of knowledge of the peculiar conditions of system best adapted to its use, rather than from the lack of efficacy in the remedy itself. It now seems well established that bromide of potassium has the power to produce contraction of the capillary blood-vessels, particularly the capillaries of the brain. It is important, therefore, when the remedy is to be administered, to determine, if possible, whether the brain is capable of resisting its action upon the capillaries. If the amount of blood thrown upon the brain is sufficient to produce capillary congestion, and consequent convulsions or epileptic fits, the administration of such a remedy as the bromide of potassium, which has the power to contract the capillary blood-vessels, will be of service; but if the brain is already without the proper supply of blood, the extra amount which will be removed from it by the action of the bromide of potassium will not only not benefit the patient, but will probably increase the force of the paroxysmal seizure.

The preparation among the bromides which he most favored in the treatment of epileptic affections was the bromide of zinc. It is to be administered in 15-gr. doses four times a day.

DELIRIUM-TREMENS.

If the case is one in which congestion is present, the administration of bromide of potassium will produce beneficial results. If there is no congestion, some other remedy is better adapted to the treatment of the case.

INSOLATION.

He had not become aware of the fact that bromide of potassium had ever been used in the treatment of this class of cases, until he used it in two cases, in which it was evident that congestion was present. In one case the man revived within a few minutes after the administration of the remedy.

CHOLERA INFANTUM.

In 1869 he read a paper upon this subject before the County Medical Society, in which he mentioned the bromide of potassium as an excellent remedy for the cure of this disease. Since that time he had received communications from different physicians, some of whom spoke of the remedy as being beneficial in the treatment of this disease, while others had received no beneficial results. Still, I insist, says the doctor, that whenever the cholera infantum is produced by either a congestive affection of the brain, such as obtains from exposure of the child to heat, or from conges-

tion of the gums in teething, there is no remedy more serviceable than the bromide of potassium. The medicine is very easily absorbed, and in many cases of swollen and congested gums he had rubbed it upon the parts, with the effect of easing the pain, removing all tendency to convulsions, and checking the bowels, and the children have recovered without any further trouble.

Whenever he has used the remedy in gastritis, he has obtained beneficial results. In these cases he always uses it well diluted with cold barley-water, which will render it more liable to be retained by the stomach.

LARYNGISMUS STRIDULUS.

In the treatment of this disease the bromide of potassium in five-grain doses, administered in the form of spray, has succeeded in his hands above all other remedies. In one case in which the remedy had been administered in this manner the child vomited and threw off a quantity of bronchial casts which were exhibited to the members of the Academy.

He advocates the use of the remedy in the treatment of diphtheria, although the profession may perhaps be inclined to regard its use in this disease as an empiricism rather than otherwise. It will, locally applied, relieve the amount of deposit and greatly mitigate the distress of the patient. He had treated one case exclusively with the bromide of potassium, and so far as the diphtheria was concerned the child was cured. The patient was doing well, when it suddenly died, probably from paralysis of the heart.

NAUSEA AND VOMITING OF PREGNANCY.

The success which he had obtained in the treatment of this condition by the use of the bromide of potassium had been most marked. In some cases the results obtained were surprisingly beneficial.

He has also found it very efficient in relieving the pain incident to

DYSMENORRHEA.

The remedy was very serviceable in

INFANTILE REMITTENT,

administered in single doses before the return of the paroxysms. In these cases, if there was any tendency to central congestion, the remedy was certain to prevent it.

It was very useful as a local remedy in the treatment of

ERYTHEMA

of children. In

PHLEGMONOUS ABSCESS

its local application, if made early, would arrest the spread of the inflammatory process, and relieve that which was already present.

It had been questioned whether the remedy could be absorbed by the skin. It was certain to be absorbed if applied in solution at a temperature lower than that of the blood.

In all hyperæsthetic conditions of the skin, such as the

ITCHING OF PREGNANCY,

the local use of the remedy was of great service.

Dr. PEASLEE remarked that he had used bromide of potassium in the treatment of the convulsions of new-born children with good success. But the distinction must be made between this condition and true *trismus*, which occurs later. In the latter condition he does not regard the remedy as at all reliable. There are two general propositions with regard to both effects produced by bromide of potassium.

In the first place, it is a very powerful cerebro-spinal sedative, and exercises but little influence upon the ganglionic nervous system.

In the second place, a similar effect is produced in the part to which it is applied locally.

It is therefore a beneficial agent used either generally or locally.

He does not regard it as a remedy to be exclusively relied upon in the treatment of disease, except in a few instances.

The combination of bromide of potassium with other remedies, in many instances, greatly increases their efficacy. For example: the bromide of potassium will be found to constantly correct the disagreeable effects of opium. In nervous women there is no more valuable remedy than the *Liq. opii odorata* of Dr. Squibb; but there are very many women with whom it does not at all agree. Under such circumstances, if bromide of potassium is combined with the opium, all the evil effects of the opium will be dispelled. When the bromide is used for this purpose it is necessary to give a sufficient dose to affect the brain. He usually prescribes a single large dose, which is to be taken a few hours before taking the opium.

There are some very anæmic women, upon whom the bromide of potassium will have no effect whatever.

The local application of this remedy in solution is of immense value in some cases of *pruritis vulvæ* and *vaginæ*. First, wash the parts thoroughly with warm water, and then make a topical application of any strength desirable up to a saturated solution. The soothing effect produced is very frequently eminently satisfactory.

In cases of *stomatitis*, *catarrh* of the *posterior nares* or *pharynx*, *nausea* and *vomiting of pregnancy*, the remedy is very serviceable. In cases of threatened

ECLAMPSIA,

which sometimes occur at the sixth or seventh month of utero-gestation, when the kidneys become inactive, it is one of the greatest safeguards against this complication which we have. Administer it in fifteen gr. doses, t. i. d.

When the eclampsia is established it is not to be relied upon.

HYPNOTIC.

The remedy is very useful as a hypnotic, but for this purpose it must be administered in such doses as will produce an effect, without any special reference to the size of the dose. Twenty to forty grains are such doses as he prescribes the first night; and if sleep is not obtained, much larger doses are given the second night. It will be found that, if the patient is in the habit of taking stimulants, much larger doses will be required to produce the desired effect. In every spasmodic cough the remedy habitually enters into the formula for his prescriptions. When the remedy is to be administered alone, it should always be given in cold water.

Dr. VAN KLEEK remarked that he had used bromide of potassium in a very large number of cases of nervous headache, the so-called "sick headache," and had found its action exceedingly beneficial.

In reply to a question from Dr. Van Kleeck, Dr. Squibb answered that bromo-camphor was of no special efficacy in the treatment of disease, and that its quackish reputation was justly on the wane.

Dr. J. C. PETERS referred to the use of bromide of lithium and sodium in chronic cases, where the bromide of potassium seemed to be worn out. A favorite com-

bination with him, when the person was pale, weak, and nervous, was with the sweet wine of iron.

B. Sweet wine of iron, $\frac{3}{4}$ iv.
Bromide of potassium, $\frac{3}{4}$ i.

M. Dose, fl. $\frac{3}{4}$ i.

By using this combination he had been able to continue the use of the bromide of potassium where, otherwise, he would not have been able to use the remedy at all.

MENORRHAGIA.

He had found the bromide of potassium a very beneficial remedy in the control of this difficulty.

DELIRIUM-TREMENS.

He had given $\frac{3}{4}$ i. of the bromide of potassium in twenty-four hours in this disease, without producing any deleterious effects, but, on the contrary, with marked benefit.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 8, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

CONGENITAL MALFORMATION OF OS COCCYX—OPERATION.

DR. SAYRE exhibited a portion of the os coccyx removed by operation from a young lady aged fourteen. The patient had a malformation of the bone in question since birth, which malformation consisted in a sharp projection backwards. In consequence of this state of things she was unable to sit in an erect position except upon a soft cushion, and would even then lean forwards to be comfortable. As she grew up the attempts to assume an erect posture would bring on attacks of chorea, and she was taken from school in consequence. On examination, the end of the coccyx was found projecting outwards and backwards, covered by a thin and shining layer of skin which was so sensitive that the least touch was sufficient to produce choreic spasms. The operation for the removal of the malformation was done with the assistance of Drs. Blake and Yale, the periosteum being carefully peeled up and the projection sawed off. The wound healed kindly, and all the nervous symptoms ceased.

MORBUS COXARIUS.—A STRIKING EXAMPLE OF THE REPRODUCTIVE POWER OF NATURE.

He also exhibited a specimen of morbus coxarius removed post-mortem from a girl, an excised portion of whose hip he had exhibited at the meeting of the society, held Jan. 14 (*vide MED. REC.*, p. 206) shortly after the operation. She was ten years of age, and had suffered from hip disease for five years. The operation was performed more for the sake of allowing her to die easier than for any hope that it might give of recovery. She lingered along until to-day (April 8) when she died of exhaustion.

An autopsy was performed with the greatest difficulty, disclosing a very interesting pathological condition. At the time of the operation, the first section of the femur was made through diseased bone, when another portion, lower down, was removed through what appeared to be healthy bone structure. At the autopsy, the bone was found to be necrosed two inches beyond the last section, but nature had, nevertheless, made a very handsome and complete involucrum on the external aspect. The acetabulum, which was perforated at the time of the operation, was

now entirely covered over by granulations. The internal periosteum corresponding to this perforation was peeled off and showed the commencement of the track of an abscess which passed underneath the neighboring muscles, as far as the posterior part of the sacrum. On the whole, no better specimen could have been presented to prove the advisability of an operation in such cases.

DR. CARO remarked that he had never heard of any such malformation of the coccyx to be due to other than traumatic causes.

VESICAL CALCULI REMOVED PER URETHRAM—CONCEALMENT OF STONE BY FOLDING OF BLADDER.

DR. CARO presented two small calculi which were of interest in a clinical point of view. One, weighing 75 grains, was extracted from a woman aged 75, who had been, for three years previous to the operation, troubled with symptoms of cystitis. She had been under the care of four physicians, all of whom agreed in calling the disease simple cystitis, and although Dr. Caro, when he was asked to attend her, suspected the existence of calculus, he was unable to substantiate the suspicion. She passed from under his charge for a while, and it was not until he was called a second time to treat her, that he was enabled to make a positive diagnosis. While withdrawing the catheter after injecting salt and water into the bladder, the instrument grated against a stone. After the bladder was empty he examined her again, but with the same result that had attended his former efforts. Dr. Little was called in consultation, but succeeded no better until the bladder was filled. When, however, the presence of the calculus was positively ascertained, Dr. Caro commenced to dilate the urethra with sponge tents. On the fourth day the calculus was extracted, the patient being during the latter part of the operation slightly anesthetized. The failure to detect the stone when the bladder was empty was explained upon the supposition that it was enclosed by a fold of mucous membrane.

The second specimen of calculus, weighing 48 grains, was also removed from a female patient, who was aged 65. While passing water one day, there was a sudden arrest of the stream, attended with severe pain. Dr. Caro was sent for, and on his arrival found her still sitting on the chamber greatly alarmed, and suffering much pain. On examination he found the stone projecting half way through the meatus, and, with a pair of dressing forceps, removed it without the least difficulty.

DR. WARD, in connection with the first case, referred to a similar one, in which the same condition of things—the folding of the stone in the mucous coat of the bladder—was verified by the finger introduced into the bladder, during an operation for lithotomy.

DR. MASON also referred to another example of the same condition, occurring in the practice of Prof. Gross, of Philadelphia.

DR. SAYRE remarked that such cases proved the necessity of always injecting the bladder before being positive, in any suspicious cases, that no calculus existed. He had met with two, in which it had been impossible to make a clear diagnosis until the viscus had been distended by an injection.

SUBACUTE MENINGITIS—ATHEROMA OF ARTERIES AT BASE OF BRAIN.

DR. S. B. WARD presented the brain and heart of a gentleman sixty years old, who had been during the past few years under the care of a number of prominent physicians of this city. The patient had enjoyed

good health up to 1858, when he left his farm to reside in the city. The first symptoms which showed themselves were those which belonged to extreme melancholy, which were referred for the most part to his leaving his old home, and which symptoms were so persistent and severe that he was unable to attend to any business for two years. Subsequently he did well until 1861, when he began to complain of a troublesome headache. He was relieved of this latter symptom by a travelling trip, and remained well until 1865, when he again suffered from headache, with vertigo. This condition of things took him from his business for four or five months. In 1871, the pain in his head returned, accompanied by loud noises, which he likened to the roaring of waters, the clashing of thunder and the snapping of pistols. The abnormal sounds troubled him very much. From this time he was seldom well, except for a few days, the pain in the head and the noises being almost constant. Sometimes he would sit for hours together, with hands joined, rolling his thumbs over each other. Such a fit would sometimes last for weeks at a time, and would be alternated with a mood for reading, the exercise of which he was but little given to while in health. He had also attacks of insanity, which made him wild, unreasonable and, as his wife thought, dangerous. At one time he evinced a suicidal tendency, and it was only by the exercise of self-control, and walking the streets for hours at a time, that this tendency was overcome.

Dr. Ward first saw him during February 1874, when he was called to pass a catheter, the patient having at that time paralysis of the bladder, and became his regular medical attendant on the month following, continuing in that capacity until the death of the patient. There was nothing particularly new in the symptoms; there never was any fever, the pulse ranging from 70 to 80 until a few days before death, when it ran up to 100. There was never any marked increase in temperature. The patient died on the second of April, and the autopsy was made on Saturday.

The diagnosis of softening of the brain had been made by many of the physicians who had seen the case, and the specimen was of especial interest with reference to that point.

At the post-mortem nothing abnormal was noticed about the scalp or skull. The dura mater was not particularly adherent, but was very much thickened throughout; in fact, all the meninges were in that condition. About three ounces of fluid blood escaped from underneath the arachnoid, and the vessels of the pia mater were very much injected. There was no point of softening in any part of the brain. The vessels at the base of the brain were in an atheromatous condition. The spinal cord was distinctly reddened, was quite hard, and the gray matter was very indistinct. The brain itself weighed fifty-two and a half ounces. The heart was perfectly healthy, and the valves, examined with great care by Dr. Satterthwaite, were found to be sufficient. On laying open the aorta a very pretty specimen of atheromatous degeneration in all its stages was observed. This condition extended into the innominate, left carotid, subclavian, and probably into all the arteries of the body. The lungs contained deposits of tubercles, recognized during life, and at the apex of the right lung there was a distinct cicatrix, as if a cavity had healed. The bronchi were in the condition of chronic inflammation. The kidneys were contracted.

Dr. Satterthwaite, in answer to a question from

Dr. Shrady, remarked that there was a new formation of vessels in the arachnoid.

In answer to a question from Dr. Knapp as to the existence of any disturbance in sight, Dr. Ward remarked that four days before death the patient insisted upon having the gas lit at noon, complaining of the darkness of the room, and from that time it was quite evident that there was total blindness.

Dr. KNAPP referred to a case in which the remarkable symptoms of nasal hemiopia was present, due to the presence of atheromatous arteries embracing the outer portion of the optic chiasm.

Dr. WARD, also, in this connection stated that the specimen which he had presented for membership to the Society was one in which a cancerous tumor of the brain was in such a situation directly over the optic commissure, that when sitting upon the growth so pressed upon that nerve-centre, as to entirely destroy vision, which condition was relieved while in the recumbent position. The patient was the son of a well-known clergyman of this city.

CANCER OF THE CONJUNCTIVA.

Dr. KNAPP exhibited a specimen of cancer of the conjunctiva, sent to him by Dr. Chapman, of Medina, N. Y. It was removed from a man seventy years of age, who in March, 1872, received a slight injury to the outer part of his eye, by a chip, while chopping wood. The inflammation of the part which followed soon subsided, and no inconvenience was experienced for four or five months. At the end of that time a small tumor made its appearance at the seat of injury, and in the course of five months gradually increased in size, until it encircled the cornea in its outer and upper portion. Then it gave rise to intense and persistent pain so that the patient insisted upon the removal of the eye, which operation was performed last May. The tumor extended back towards the equator two or three lines into the conjunctiva, and the cornea was opaque. The specimen was sent to Dr. Knapp for examination, who discovered it to be a case of epithelial cancer commencing in the conjunctiva and extending into the cornea at its junction with the sclerotic, penetrating into the corneal corpuscles and dilating them, presenting under the microscope a beautiful anastomosis of strings of epithelioid cells. The specimen was very satisfactorily exhibited under the microscope to the members.

Dr. ELSEBERG, in remarking upon the specimen, thought it of great interest, particularly in regard to fixing the fact of the traumatic origin of cancer. He had seen a similar case ten years ago.

The Society then went into Executive Session.

Correspondence.

NOTE ON THE HISTORY OF SYPHILIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR,—The following note on the history of syphilis, kindly sent me by Frank L. James, Ph. Dr., M.D., Osceola, Miss. Co., Ark., deserves to have been communicated directly to your journal, and I desire to give it the same publicity which only the modesty of my correspondent prevented him from doing. The fact that syphilis was regarded as a new and hitherto unknown disease by the physicians of the latter part of the fifteenth century, and was believed to have arisen at the siege of Naples, is universally acknowledged even by the advocates of its more ancient ori-

gin, but the quaint and additional items of proof here adduced cannot fail to be of interest:

"I have taken the liberty of addressing you for the purpose of pointing out a few links in the chain of evidence tending to show that syphilis had its origin in Naples, or at least that it was carried thence to France by the soldiers of Charles VIII. Francis Rabelais, one of the first physicians of his time, a man of wonderful erudition and a great traveller, mentions the pock (vrole) in almost every page of his remarkable book, 'Gargantua and Pantagruel.' One of his heroes (Panurge) frequently speaks of his 'having the blessed fruit of the great pox,' of 'having gathered the ripest,' etc. In several places he speaks of having 'been anointed' for the pox, and in one instance he speaks of 'mercury being the patron of all those that have the great pox,' showing that as early as his time this specific was known.

"Now Rabelais was born in Chinon about 1480, and when Charles VIII. and his soldiers returned from Naples, was a youth of some fifteen years of age. He was wonderfully precocious, and even at that age was far ahead of most of the physicians of his day.

"In M. le Duchat's *Vie de Rabelais*, the following anecdote is told of him: Kneeling one day in front of a statue of Charles VIII. in a church at Mèzières (I think it was), a monk, thinking that Rabelais mistook the figure for a statue of a saint, went to him to apprise him of his error. 'I am not so much of a block-head as thou thinkest me,' replied Rabelais; 'nor yet so blind as not to know that I am kneeling before the statue of King Charles VIII., for whose soul I am praying, because he brought the pox out of Naples into France, by which I and other physicians have been great gainers!'

"A great many stories of Rabelais are apocryphal, but this one is told as true, and from his well-known character bears the impress of truth. It is alluded to by Budé (author of *Epistolæ Græcæ*). Sorel in the *Bibliothèque Française*, and I believe finds a prominent place in all editions of Rabelais.

"Here, then, we have the testimony of the most learned physician of his time, a contemporary of Charles VIII., and of the appearance of the pox, who unequivocally says that it came out of Naples."

Respectfully yours,

F. J. BUMSTEAD.

32 W. 36TH ST., NEW YORK, March 13, 1874.

THE COMPARATIVE VALUE OF MOLESWORTH'S DILATOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—I desire to call the attention of the profession to a dilator invented by Dr. Wm. Molesworth. He designed it especially as a substitute for Barnes's dilator for the uterus, but it may be applied with equal or greater advantage to other organs. First, as to its relative value as a dilator of the uterus. A case in which I had occasion to use it a couple of weeks ago will demonstrate one of its advantages over Barnes's instrument. It was a protracted case of labor, in which the delay was occasioned by an unusually tedious dilatation of the cervix, after it had proceeded naturally to a certain extent. Having no medical assistance, I attempted to dilate with Barnes's dilator, which I have always found to be a very reliable, though sometimes a troublesome instrument, but, having to use the pump, and handle the stop-cock with one hand, while I attempted to keep the dilator *in situ* with the other, I

had to desist, after it had repeatedly slipped in and out of the uterus, generally the former. In the earlier stages of pregnancy and of labor this difficulty, however, is not so likely to occur. I now sent for my Molesworth dilator, passed in the largest size easily, held it in place with one hand, while I pumped in syringeful after syringeful of water, until seven were introduced (not using the screw at all), without any delay or a single slip. In fact, it is almost impossible for it to slip, for two reasons: one, the firm handle (the syringe) by which it is held, or the rod attached to the syringe, and the peculiar surface presented by the rubber tube, very different from that of Barnes's bags. If it be discovered, after the dilatation and consequent shortening of the tube, that it has been introduced a little too far into the uterus, it may be drawn gradually out, pushing the cervix with the fingers of the other hand gently over it, as we sometimes do over the head of the child in the natural process. This manoeuvre cannot be practised with the other instrument. This instrument is therefore preferable for the country practitioner, who is often compelled to act without medical aid; but is a more powerful instrument, and requires a little more care. Another advantage, and no mean one for the country physician especially, is the lessened liability to rot and become useless, when not frequently employed, since the sides of the tubes do not come into contact, and they dry more readily when left exposed for a time after draining.

I have been much pleased with its comparative superiority over the rubber rectal dilator of Whitehead. I have lately been using both in the same case; and though the latter, with the addition of the silk bag described by this writer, gave good results, I found the former more convenient and more effective, but of course requiring a little more care and judgment.

Seeing at once the adaptability of this instrument to the treatment of strictures of the *œsophagus*, I immediately had Mr. Stohlmann, of the firm of Tiemann & Co., prepare for a case which I had on hand, an *œsophageal* tube which fits the instrument, and by means of which his smallest tube can be passed into almost any stricture which may present itself at any point of the *œsophagus*. His tubes are so small that they obviate entirely the necessity for sponge-tents as preparatory to the dilatation of the cervix uteri, or of conical bougies in stricture of the *œsophagus*.

It has recently been recommended by several writers, as by Dr. Ellinger, of Stuttgart, and by Dr. William Ball, of Brooklyn, New York, to dilate the cervix uteri "forcibly and rapidly," for the relief of dysmenorrhœa, and for other purposes; and they describe instruments designed by them for that purpose; but I doubt if any metal instrument can equal, in safety or efficiency, India-rubber tubing distended by hydraulic pressure.

In the February No. of the *London Lancet* (Am. edit.), J. Joap, of Australia, describes a new dilator for stricture of the *œsophagus*, "combining the principles of Thompson's urethral dilator and the bougie à boule." With this he succeeded well. But it is manifestly far inferior, in safety at least, to the one here recommended; first, because it is *straight* and *rigid*, secondly, because it cannot dilate as uniformly; and thirdly, because in withdrawing, it is apt to entangle and injure the mucous membrane.

FREDERIC D. LENTE, M.D.

New Instruments.

IMPROVED POSTERIOR NARES SYRINGE.

By L. C. WARNER, M.D.

I wish, through the columns of THE MEDICAL RECORD, to describe an improved syringe for making applications to the nares and pharynx, which I think possesses several advantages over any other instrument heretofore employed for this purpose. Messrs. Tieman & Co. first constructed this syringe for me several years ago, and I have since used it quite extensively in my own practice, but I am not aware that any description of it has ever been published so as to make it generally known to the profession. It consists of a hard-rubber point or mouthpiece, connected to a common rubber bulb by about six inches of rubber tubing. The hard-rubber point is about seven inches in length, and terminates in a small, olive-shaped bulb, which is perforated by several small holes. One peculiarity of this point is, that it has two curves, passing in reverse directions, as shown in the accompanying plate: one an inch from the olive-shaped bulb, and the other about two inches from the opposite end. The space between the two curves is about equal to the distance between the pharynx and lips, so that when the syringe is introduced into the mouth, the point passes up behind the uvula, while the opposite end drops down in the direction of the chin.

The principal advantage of this instrument over the ordinary posterior nares syringe is the greater ease with which it may be used. The shape of the syringe is such that, being introduced into the mouth, the point naturally finds its way up behind the palate. Besides, in discharging the syringe, the point can be held perfectly still—a result which it is impossible to obtain with a piston syringe.

The difficulty of using the ordinary posterior nares syringe is so great that it has never come into general use, but its place has largely been taken by Thudichum's apparatus, or what is commonly called the nasal douche. I do not propose here to discuss the relative merits of these two methods, but will only say that careful observation and experiments have satisfied me that applications made from behind the palate are used with less discomfort, and cleanse the cavities of the posterior nares much more thoroughly than those made from the nostril. I also fully concur with Dr. Roosa in the opinion that the posterior nares syringe is a much safer instrument than the nasal douche.

My principal object in devising this syringe was to get an instrument which patients could use in their own throats. I found many of my patients so situated that they could not visit me oftener than once or twice each week. This, in most cases, was frequent enough for the stronger applications; but I desired, in addition, to keep the parts thoroughly cleansed by using mild applications, like salt and warm water, two or three times each day. In supplying this want, the syringe has more than met my expectations. Patients,

after a little instruction and a few trials, will use it better on themselves than the physician can use it for them.

In connection with the use of the syringe, I have found great benefit from gargling the throat after the method recommended by Prof. Troltsch. This method may be briefly stated as follows: Let the patient sit, or better, lie down, with the head thrown well backward, and, taking a small swallow of water, make repeated swallowing motions, without, however, admitting the water into the stomach. This method will be found to reach and cleanse the pharynx much more thoroughly than the noisy gargling usually practised.

119 WEST FORTY-FIRST STREET, NEW YORK.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 5, 1874, to April 18, 1874.

BAXTER, J. H., Chief Medical Purveyor.—To report to the Surgeon General for assignment to duty. S. O. 83, A. G. O., April 16, 1874.

HEAD, J. F., Surgeon.—Granted leave of absence for 20 days, on Surgeon's certificate of disability. S. O., 65, Dept. of Dakota, April 3, 1874.

IEGER, A., Surgeon.—In addition to his present duties, during absence of Surgeon Head, to perform the duties of Medical Director of the Department. S. O. 65, c. s., Dept. of Dakota.

BAILY, J. C., Surgeon.—To report in person to the Commanding General Dept. of the South for assignment. S. O. 78, A. G. O., April 10, 1874.

BROWN, H. E., Assistant Surgeon. Granted leave of absence for 30 days, with permission to apply for an extension of 30 days. S. O. 52, Dept. of the Gulf, April 1, 1874.

MIDDLETON, P., Assistant Surgeon.—Relieved from duty in Dept. of the South, and to report in person to the Commanding General Dept. of Texas for assignment. S. O. 78, c. s., A. G. O.

DEWITT, C. Assistant Surgeon.—To report in person to the Commanding General Dept. of the South for assignment. S. O. 78, c. s., A. G. O.

GIRARD, A. C., Assistant Surgeon.—Granted leave of absence for four months with permission to go beyond sea, on Surgeon's certificate of disability. S. O. 79, A. G. O., April 11, 1874.

PORE, B. F., Assistant Surgeon.—Relieved from duty in Dept. of the South, and to report in person to the Commanding General Dept. of Texas for assignment. S. O. 78, c. s., A. G. O.

CAMPELL, A. B., Assistant Surgeon.—Assigned to duty at Ringgold Barracks, Texas. S. O. 54, Dept. of Texas, March 30, 1874.

STEINMETZ, W. R., Assistant Surgeon.—Relieved from duty in Dept. of Texas, to proceed to Baltimore, Md., and, on arrival, report by letter to the Surgeon General. S. O. 78, c. s., A. G. O.

HARVEY, P. F., Assistant Surgeon.—Relieved from duty in Dept. of Texas, to proceed to Burlington, Iowa, and, on arrival, report by letter to the Surgeon General. S. O. 78, c. s., A. G. O.

Medical Items and News.

CREMATION.—The cause of cremation (writes a German correspondent of the *British Med. Jour.*) appears to be rapidly gaining ground. The merits of the new system of disposing of dead bodies are shortly to be tested by practical experiment in Saxony, the two principal towns of which, Dresden and Leipzig, have offered to legalize it, as an optional course, supposing its advocates can practically make good their assertions in its favor. A furnace for cremation is now actually in process of construction by Herr Friedrich Drenens, a Civil Engineer. Its cost is estimated at 5,000 marks, or £250; and it is calculated that the complete combustion of a human corpse will take about an hour. The number of persons who have enrolled themselves as members of the Cremation Society in Zürich amounts to at least four hundred. Professor Weith has gone to Italy, to consult with the professors there who are engaged in studying the practical methods of burning the body.

A Philadelphia paper of the 19th inst. contains a long account of an instance of cremation in that city. A physician, whose son died on the Tuesday previous, erected a furnace in the cellar of his house, and reduced the body to ashes.

DR. B. W. MCCREADY.—(*Extract from minutes of Medical Board of Bellevue Hospital.*)—Dr. Clark, Chairman of the Committee on the resignation of Dr. McCready, presented the following report:—

The Medical Board of Bellevue Hospital cannot part with their long-tried and so worthy associate, Dr. Benj. McCready, without expressing their regret that he has found himself compelled by resignation to sunder official relations which have been in a high degree agreeable and profitable to all its members.

In twenty-five years of associated labor they have learned to appreciate him as a scholar, a learned and skilful physician and a gentleman. The example of his punctuality in duty, the application of his large stores of medical knowledge to the relief of the sick, his wise counsels in the management of the hospital, his uniform courtesy to all his colleagues, his kindness and devotion to the sick under his charge, the clinical instruction by which he has greatly aided in forming and storing the minds of the hospital pupils and his professional eminence are the prosperity of the institution, and make up part of its history.

In his retirement from hospital duties he takes with him the highest respects and the best wishes of this Board.

A. CLARK,

Chairman of Committee.

ISAAC E. TAYLOR,

President of Med. Board.

ACTION AT LAW FOR A DEATH FROM CHLOROFORM.—A Madame Caron some months since was taken by her husband to a dentist at Lille, to have a tooth drawn. Chloroform was administered in his presence, and his unfortunate wife died. The dentist was condemned by the Criminal Tribunal at Lille to a month's imprisonment and 500 francs fine for "homicide by imprudence." On appeal, the imprisonment was struck out of the sentence. Thereupon the husband, although he had completely authorized the use of the chloroform, brought a civil action for damages, demanding 20,000 francs in his own interest and that of a son, a minor. The tribunal, considering the fact of homicide by im-

prudence having been established by the judgment of the criminal court, condemned the defendant to pay 4,000 francs damages, 1,000 to go to the husband and 3,000 to be put out at interest for the son until he attained his majority.—*Union Med.*, December 11.

ALUMNI ASSOCIATION OF THE ALBANY MEDICAL COLLEGE.—We have received a circular addressed to the Alumni of the Albany Medical College, together with a copy of the Constitution and By-Laws of the Alumni Association. The circular requests all graduates to send to the Secretary, Willis G. Tucker, "without delay, their present addresses, and also those of other graduates with whom they may be acquainted, especially of those in their immediate vicinity." It is proposed making a complete catalogue of the Alumni.

HOSPITAL APPOINTMENTS.—The following is a list of the recent appointments to the resident staff of Bellevue and Charity Hospitals:

Bellevue: Fred. S. Dennis, A.B., M.D., Junior Assistant; Geo. F. Bates, M.D., G.M. Stoeckel, M.D., G. R. Metcalfe, A.B., M.D., J. M. Hills, A. B., M.D., F. C. Ainsworth, M.D., R. F. Dearborn, A.M., M.D., Provisionals.

Charity: Dr. M. A. Alvarez, J. R. Joininez, Nicholas C. Jobs, Francis Hustase, Wm. D. Spencer, James J. Delancy, Edward T. Ely and Edward M. Hill.

RETIREMENT OF PROF. HYRTL.—Dr. Hyrtl, the eminent professor of anatomy in the University of Vienna, delivered his final lecture on the morning of the 16th of March, and in the afternoon of the same day met an assemblage of over three thousand pupils and friends, who presented him with addresses and other evidences of esteem. He was the recipient also of over fifty congratulatory telegrams from various parts of the world, and on the following day the municipal council of the city conferred upon him honorary citizenship.

USE OF WARM AND HOT WATER IN SURGERY.

By PROF. FRANK HASTINGS HAMILTON, M.D.,

NEW YORK.

IN the January number for 1873, of the *Richmond and Louisville Medical Journal*, I have published a paper, originally read before the New York Reading-Room Association, on the subject of warm water in surgery, and which was summarized in THE MEDICAL RECORD. The paper includes an account of ten cases of surgical accidents and operations, treated mainly by submersion in warm or hot water, with allusion to many other minor examples treated in the same manner at St. Francis' Hospital, the Reception Hospitals, and Bellevue; all occurring under my immediate observation. The practice was first introduced (from the German hospitals) at St. Francis' Hospital of this city by my colleagues and predecessors, all German physicians. The results have proved so remarkable that I felt constrained to place them before the profession. I am now able to add several other cases, and although they include one in which death has resulted, yet my confidence in the plan has not diminished.

CASE II.—*Traumatic gangrene arrested by hot-water submersion; spontaneous separation of foot and leg on the ninth day after submersion; recovery.*

Hugh Quigley, et. 26; admitted to 99th Street Reception Hospital, Dec. 8, 1873, with a fracture of the right leg, caused by the fall of a heavy stone upon the leg about one hour before admission. The bones were broken near the junction of the lower and middle thirds. There was a slight laceration on the inside of the leg; the posterior tibial artery pulsated distinctly. Dr. Delgado, the house-surgeon, applied a roller and placed the limb in a box padded with oakum.

Dec. 9. A padded leather splint was applied to the outside of the leg and secured by a roller.

Dec. 10. 4.30 P.M., foot found to be cold, congested, and edematous; pulse 130; splint and bandage removed, and limb wrapped in cotton batting, with hot bottles.

Dec. 11. I was summoned. There was then no sensation below the point of fracture; the pulsation of the posterior tibia had ceased; the leg was swollen and erysipelatous to a point some inches above the knee, and gangrene had extended in patches to about the middle of the leg.

It was apparent that the condition of the limb and of the patient were in the highest degree unfavorable for an amputation, which, in case it were made, must be above the knee. Surgeons need not be reminded how seldom an amputation at this period (intermediate), and under these circumstances, is successful.

Dr. Delgado, by my suggestion, made several incisions through the gangrenous tissues, and at once placed the limb in a water-bath at a temperature of about 110° Fahrenheit. No medicine.

Dec. 12. Pulse 112; temperature 103½.

Dec. 13. Pulse 119; temperature 99½.

Dec. 14. Pulse 114; temperature 101½. Swelling of limb above the fracture increasing. Permanganate of potassa and chloride of zinc put in the water as disinfectants. Stomach rejects food; bowels are constipated; appetite poor. Bicarbonate of bismuth ʒi. ter die.

Dec. 15. Pulse 104; temperature 97½. Vomiting has ceased. I saw him to-day for the first time since the limb was submerged. The water in the bath has been changed twice daily. The patient seems cheerful; says he sleeps very well, has no pain in the limb, nor is it particularly tender upon pressure above the line of gangrene. I cannot see that the gangrene has extended at all since the present treatment was adopted.

Dec. 16. Pulse 90; temperature 98.

Dec. 17. Pulse 96; temperature 99.

Dec. 19. The erysipelas has disappeared, and the line of demarcation is formed near the junction of the lower and middle portions of the leg. This is the eleventh day since the injury was received, and the eighth since submersion was employed. With my forceps and scissors I proceeded to trace the separation, and soon found that all the dead tissues were separated, except a portion of the gastrocnemius and soleus, which latter I divided with a knife, low down, and the limb fell off at the point of fracture; the incision of these muscles causing only a moderate hemorrhage from very small vessels. These I tied; neither anesthetics nor the tourniquet were employed. The stump was then covered with warm-water dressings, supported by a snug roller.

Dec. 21. Pulse 92; temperature 100°. Leg again immersed in warm water.

Dec. 25. Limb removed from bath. Granulations abundant. Dec. 28. Balsam of Peru substituted for the water as a dressing. Dec. 30, a small abscess was opened which had formed near the knee; discharged about three ounces of pus. Jan. 24, 1874, I removed the projecting and exfoliated portion of the tibia with my fingers. Jan. 31. Patient sits up in his chair two hours daily, and the stump is closing rapidly. It is quite probable, however, that at some future time it will be necessary to resect portions of both the tibia and fibula, in order to give a proper shape to the stump. I have since made resection, and the stump is nearly well.

CASE XII.—*Lacerated and contused wound of foot, with fracture of bones, caused by a car-wheel; gangrene and recovery.*—Bernard Monahan, et. 45, admitted to 99th St. Reception Hospital, Jan. 11, 1874, with a compound fracture of the left foot, caused by its having been traversed by a street-car a short time previous to admission. The foot below the tarsus was much lacerated, and several of the bones were broken. The right foot was also slightly injured.

On the following day I was summoned to decide the question of amputation. It was determined to employ submersion, in the case of the left foot, with water at a temperature of 100° Fahrenheit. The right foot was enclosed in water-dressings and placed in-bed.

Jan. 19. Left foot edematous, but not tender or painful. The second and third phalanges of the second toe have dropped off.

Jan. 20. The second and third phalanges of the second toe dropped off. Patient ordered extras, as food and tonics. Foot taken from bath at night.

Jan. 31. Right foot is well; left foot granulating and cicatrizing; water-dressings discontinued and balsam of Peru substituted.

The condition of the pulse has been recorded each day, and at no time during the progress of the case has it exceeded 80 in the minute. There has been no fever.

CASE XIII.—*Excision of head of metatarsal bone of great toe for valgus hallux.*—Adult male. St. Francis' Hospital.

Operation.—February 2, 1874. The patient having been placed under the influence of ether, Dr. Schar-

I then applied Esmarch's bandage from the toes to the middle of the leg. I then made a crucial incision over the lower portion of the metatarsal bone, rather upon its inner and dorsal aspect. In attempting to pass the chain-saw it was broken, and the section of the bone was made with the bone-cutter; in consequence of which the bone was divided irregularly. After disarticulation of the head the bursa was found to communicate with the joint, and the joint-surfaces were slightly carious. During the operation not one drop of blood appeared in the wound; but there was a slight oozing of serum, which required to be removed once or twice by the sponge. The ligature remained upon the leg about twenty minutes, and when it was removed, quite a free bleeding occurred; which was, however, promptly arrested by the application of carbolic-acid water—ten drops of the saturated solution to an ounce of water.

In order to avoid secondary hemorrhage the foot was treated with cool-water dressings until the following morning, when submersion in warm water was substituted, and this was continued about two weeks. One small abscess formed and opened upon the top of the foot, about two inches from the wound. In all other respects the progress of the recovery was uninterrupted. March 20, the wound was healed.

CASE XIV.—*Valgus hallux*.—Excision of head of metatarsal bone of great toe.—Male, *et.* 18, admitted to St. Francis' Hospital, Feb., 1874, with valgus hallux in both feet, which had existed several years.

The right foot troubled him most, the integument over the articulation being almost constantly inflamed. It was decided to practise excision only upon this foot.

Operation, Feb. 9, 1874, assisted by Drs. Rose and Scharlau.—The patient was anesthetized and Esmarch's bandage applied. The incisions were the same as in the preceding case; but the section of the bone was made with the chain-saw. No blood appeared in the wound until the Esmarch band was removed. The blood then flowed quite freely, but in a few minutes it ceased spontaneously, the total amount of blood lost not exceeding two or three ounces.

The wound was treated with cool-water dressings until the following morning, when the warm-water bath was substituted. The bath was used about fourteen days, and warm-water fomentations were then substituted. March 20, the wound was closed and patient was walking about, the progress of the case toward recovery having been from the first uninterrupted.

CASE XV.—*Lacerated wound of hand*.—*Submersion on the seventh day*.—*Death on the thirteenth day*.—Andrew Bedhman, *et.* 27, admitted to Bellevue Hospital, Dr. Wood's service, Jan. 12, 1874. His left hand had been caught in a "moulding machine" a few hours before admission, and was "terribly lacerated—in short, all torn to pieces." By advice of Dr. Wood, the acting house-surgeon proceeded at once to amputate the first and third fingers, through the middle of the metacarpal bones, and the second finger at the second joint. Only one or two vessels required the ligature. The hand was then laid upon a splint and dressed with carbolic-acid solution and lint.

Jan. 16th. A consultation was called by Dr. Wood, at which I was present. Hand greatly swollen and wounds gaping, foul, and gangrenous; redness and swelling extending above the wrist; pulse, in the morning of this day, 100; in the afternoon, 120; temperature, 106; respiration, 20; patient very despondent. The period and condition seemed peculiarly unfavorable for amputation, and it was decided to employ

warm-water submersion. We subsequently learned that no bath could be obtained until the 19th. On this day (16th) he took quin. sulph. gr. x. at 6 and 9 P.M., also tr. aconite, Fleming, $\mathcal{R}ij.$, at 6, 7, 8 and 9 P.M.

On the 18th he had a slight chill.

Jan. 19th. "Hand begins to look a little better; some healthy discharge;" but most of the wound is "still foul and offensive." House-surgeon ordered sodæ sulphitis, gr. xv., and quin. sulph. gr. v. ter in die.

Jan. 20th. Some improvement in the appearance of the granulations; pain in shoulder.

Jan. 22d. Opening made above the wrist to let out pus. 23d. Explored again for pus, but none found. 24th. For the first time the submersion has been continued all night.

Jan. 25th. At 5 P.M. the night watchman, in making his rounds, discovered that the hand was bleeding, "which was arrested by the orderly before the acting house-surgeon could arrive (which was in two minutes). Patient had lost very little blood (water in bath hardly tinged), but was terribly frightened." He was informed that he had lost very little blood, but from this moment he failed rapidly and died about three hours later.

Remarks.—The records of the autopsy cannot be found, but it is understood that there was no evidence of pyæmic infection. The period at which submersion was commenced—the sixth day—renders it apparent that the water treatment had little or no responsibility for the final result. It is my opinion, founded upon my experience in similar cases, that submersion, practised from the first or second day after the accident, would have saved his life.

The following is the record of temperature and heart's action from and after the fourth day:

Jan. 16th. (Day of consultation) P.M. Temperature 106°; pulse 120.

Jan. 17th. (Fomentations commenced) P.M. Temperature 106½°; pulse 108.

Jan. 18th. (Slight chill.)

Jan. 19th. (Submersion commenced to-day) P.M. Temperature 102½°; pulse 108.

Jan. 20th. Temperature 103½°; pulse 112.

Jan. 21st. Temperature 106°; pulse 112.

Jan. 22d. (Incised for pus.) Temperature 103°; pulse 112.

Jan. 23d. (Explored for pus, none found.) Temperature 100½°; pulse 112.

Jan. 24th. (In bath all night.)

Jan. 25th. Died at 8.20 A.M.

CASE XVI.—*Large bursa of wrist*.—*Incision and submersion*.—*Results negative*.—A blacksmith presented himself at my office with a very large bursa on the back of his hand and forearm—probably seven inches in length by three in breadth, and by which he was completely disabled.

In February of this year I opened the bursa at two points (at Bellevue Hospital) and had the arm at once submerged in warm water. The openings did not prove to be sufficiently free to allow of easy ingress and egress of water, and the consequence was that when suppuration took place the matter made an exit at two or three other points; but at no time was the inflammatory reaction violent.

March 25th. The wounds are nearly closed, and it is apparent that a cure may be promised. In order to compare the results in this case with other similar cases, I will mention that about the same time a similar bursa of the arm was opened by one of my colleagues at Bellevue, and treated by injection of

tin, of iodine. A very smart inflammatory reaction resulted, with suppuration, and several openings formed for the discharge of pus. . . . A few days since a patient was brought to me by Dr. Cox, of Harlem, with a similar bursa, which had opened spontaneously at various points, and was accompanied with purulent infiltrations between the metacarpal bones.

Remarks.—On the whole, I am satisfied that of these three examples the case treated by submersion did the best, yet the value of this plan can only be demonstrated when the water has perfectly free ingress and egress. In a like case I would hereafter lay open the whole length of the bursa.

Method of Using the Warm-Water Bath.

For the arm and hand we have an oblong zinc bath, 23 inches long by 8 inches wide and 8 in depth, with somewhat flaring margins where the arm is to enter, supplied with a movable cover, which leaves an opening for the arm, and provided with a stop-cock to enable us to draw off and renew the water. Along

Bath for arm, forearm, and hand.

the upper and outer margin of the bath are arranged small wire-pins, upon which pieces of cloth may be fastened for the purpose of suspending the limb. Care must be taken not to allow the limb to rest against the edge of the bath, so as to interfere with the circulation, and it must be carefully adjusted upon a shelf, beside the bed, in such a position as will be most comfortable to the patient.

For the lower extremity a zinc bath is used also, somewhat larger, the floor being in the form of an inverted roof, the apex of which is below; the base being represented by the open top of the bath; this latter is provided also with a movable cover. The

apex is supported by a wooden frame and horizontal board. This bath is, like the arm-bath, provided with pins for suspension of the limb, and a stop-cock.

In the case of the foot-bath, when it is found uncomfortable to project the foot from the side of the bed, the portion of the bed upon which the body reposes is elevated by mattresses, and the bath is placed on the floor of the bedstead.

We have not thought it necessary to keep the water

at an absolutely uniform temperature, so that its management is left very much to the judgment of the patient or of his attendant; but usually it has been kept at such a temperature as to feel warm to the hand of the attendant—and this is found to be about 95° Fahrenheit. Sufficient uniformity has been attained generally by changing the water three times daily.

In case of a recent wound, where secondary hemorrhage is at all liable to occur, the limb is dressed for a few hours with either warm or cold fomentations, and is left reposing in bed; but neither sutures, adhesive plasters, nor bandages are applied. At the expiration of this time either the bath or the warm-water fomentations are commenced, and thereafter employed systematically. The patient is at liberty at any time to lift the limb from the bath, and he generally does this pretty often, to see how it is progressing.

The baths in use by us are constructed by Otto & Reyners, surgical instrument-makers, No. 64 Chatham street.

In using the fomentations we envelop the wound and limb in several folds of sheet lint or soft old muslin, saturated with warm water, the whole being enclosed in oiled silk or vulcanized rubber. This is changed about once in four or six hours.

SUMMARY OF CONCLUSIONS.

Effect of Submersion in Warm and Hot Water.

No treatment hitherto adopted, under our observation, has been attended with equally favorable results.

Under this plan the area of acute inflammation is exceedingly limited; erysipelatous inflammation has been almost uniformly arrested or restrained, when it has actually commenced, and it has never originated after submersion; gangrene has in no instance extended beyond the parts originally injured, and when progressing it has in most cases been speedily arrested (in gangrene hot water, or water at a temperature of from 100° to 110° Fahrenheit, is to be preferred). Septicæmia and pyæmia have not ensued in any case in which submersion has been practised from the first day of the accident. Purulent infiltrations and consecutive abscesses have been infrequent, and always limited to the neighborhood of the parts injured, and of small extent. Traumatic fever, usually present after grave accidents, when other plans of treatment have been pursued, as early as the third or fourth day, has seldom been present when this plan has been adopted, and in no case has the fever been intense or alarming.

The phenomena usually observed in cases of recent lacerated or incised wounds, when submerged, are, a sense of comfort, yet not absolute relief from pain; on the second or third day the parts adjacent are swollen, but not much reddened; the integument generally assumes a white and sodden appearance, and with only slight tenderness. On the fifth, sixth, or seventh day the swelling is greater than usually accompanies other plans of treatment; and, with the inexperienced, is likely to excite alarm, but it is found not to be attended with increased tenderness, and it pits under pressure, showing that it is a condition of œdema chiefly. At this time the granulations are generally covered with lymph, or some exudate of a whitish color, and which might easily be mistaken for a diphtheritic deposit. At the end of fourteen days, or thereabouts (the period at which, in most cases, we substitute fomentation for submersion), the limb is still œdematous, the granulations are abundant, sometimes presenting a fresh, red appearance, and at others covered with the white exudate.

Effects Ensuing from the Substitution of Fomentation for Submersion.

Pursuing the clinical history of these cases, we find that after fomentations are commenced, the oedema gradually lessens, but its final disappearance is delayed sometimes to a period beyond the complete cicatrization, so that the cicatrix, not unfrequently, is considerably depressed below the level of the sound parts; and we have seen this condition of the parts continue for many months. We observe, also, that the granulations are red and abundant, and that cicatrization progresses as rapidly as under any other plan of treatment; indeed, we are inclined to think that it progresses more rapidly than we are accustomed to see where other plans, considered appropriate, have been adopted. We speak especially of the vigorous appearance of the granulations, and of the cicatrization, because our opinion was, before observing these cases, that warm-water fomentations and warm baths would render granulations weak, pale, and sodden, and retard cicatrization. If such effects have resulted, they must have been presented as rare exceptions, since we have not observed them.

After Erysipelas has actually Commenced.

We have had very few opportunities of testing warm-water submersion after erysipelas has actually invaded a limb, since at St. Francis', where most of these observations have been made, erysipelas is generally prevented; but in two or three examples, imperfectly managed, at Bellevue Hospital, the results have at least furnished no testimony which would deter us from a further trial. In explanation of this latter statement, relating to Bellevue Hospital, it is necessary to say that, with one exception, the bathing-tubs employed were improvised and were imperfect, the amount of attendance during the night is too limited to insure faithful attention to the temperature of the water, the heat of the wards is greatly lowered, and none of the nurses have experience in the management of the baths.

Value of Hot Water in Traumatic Gangrene.

The power of hot-water baths, or water at or above the normal temperature of the blood, to arrest traumatic gangrene is remarkable; and the writer entertains a hope that its efficiency may not be limited to traumatic gangrene alone, yet this remains to be proven.

To what Class of Cases Submersion is especially Applicable.

Position of injury.—The lower extremities can only be completely and permanently submerged to a point three or four inches below the knee, and the upper extremities to a point a few inches above the elbow; consequently, submersion is limited to those portions of the extremities which are below the points mentioned.

Character of injury.—Submersion in warm water demonstrates its superiority over other plans, especially in the case of a laceration or contusion of the hand or of the foot, when the integument and flesh are extensively torn—provided the limb is submerged without closing the wound—that is, without sutures or bandages; indeed, sutures are inadmissible when this plan is adopted, since the oedema which almost inevitably ensues would break away the sutures.

More contusions, without external lesions, have been treated almost constantly at St. Francis' by this method; and the results have been in all cases satisfactory, and

occasionally they have progressed toward recovery in a manner to excite surprise.

Simple incised wounds have seldom been subjected to immersion, since it inevitably defeats union by first intention. Nor have wounds caused by amputation been treated in this manner, partly for the reason just given, and partly because of certain apprehensions that the depending position might expose the patient to the dangers of a secondary hemorrhage where large arteries have been severed and are exposed in the wound.

Warm-water fomentations are regarded by us as always second in value to submersion in the prevention and cure of inflammation, and they are reserved, therefore, for those examples in which submersion for one or another of the reasons already given, cannot properly be employed.

Fomentations are employed by us after about the fourteenth day in all those cases in which we employ submersion at first—occasionally, when the patient is weary of the confinement of the bath, the limb is taken out and fomented during the night.

We employ fomentations in amputations and other incised wounds when union by first intent is desired; in lacerated and contused wounds which cannot be subjected to immersion; in most examples of old ulcers; in many syphilitic and cancerous sores; in some simple contusions and sprains. In short, to repeat what has been already intimated, with warm water, either in the form of the bath or fomentation, we treat nearly all surgical accidents. Carbolic acid, the chlorinate of soda or lime, and other antiseptics being reserved for very rare and exceptional cases. Unguents and poultices are almost unknown at St. Francis'.

THE USE AND COMPARATIVE MERITS OF THE BICHLORIDE OF METHYLENE AS AN ANÆSTHETIC.

By BENJ. F. DAWSON, M.D., Etc.,

NEW YORK.

(Read before the New York Medical Library and Journal Association, April 17th, 1874.)

WHILE in London during June, 1872, I had the pleasure of being invited by Mr. T. Spencer Wells to assist him in a case of ovariectomy, in which he wished to test the merits of my clamp for the pedicle.

Aside from the great skill of this distinguished surgeon, I was much attracted by the appearance and behavior of the patient under the anæsthetic, as well as by the manner in which the latter was administered. In appearance the patient seemed to be in a natural sleep; neither her color nor respiration indicating that she was in a state of unnatural unconsciousness.

At the conclusion of the operation I was still more surprised to see how rapidly she recovered consciousness, not more than two minutes elapsing from the painless introduction of the last stitch and complete consciousness, shown by her opening her eyes and addressing Mr. Wells. There was no complaint of either nausea or headache.

On inquiry, Mr. Wells informed me that the anæsthetic used was the bichloride of methylene, or chloromethyl, as it is commonly called, and that he had used it for some time in preference to all other anæsthetics, for the reasons I will hereafter mention.

On my return home I brought with me a supply of chloromethyl, and the apparatus by which it is gener-

ally administered, and for the past two years I have used it, for myself and others, in both brief and prolonged operations.

The composition of bichloride of methylene is CH_2Cl_2 . It is a clear liquid, with an odor somewhat sweeter than chloroform, boils at 88° Fahrenheit— 54° lower than that required by chloroform—contains one atom more of hydrogen and one less of chlorine than the latter.

It resembles ether in being inflammable in air, but is more volatile, of more agreeable odor, and less irritating to the air-passages.

Chloromethyl was introduced, as a general anæsthetic, in 1867, by Dr. B. W. Richardson, of London, who administered it for the first time in October of that year, in a case of ovariotomy performed by Mr. Wells, having previously subjected himself to its effects.

Since 1867 it has been extensively used in many of the largest hospitals of Europe, as well as in the practice of many English surgeons, by many of whom, notably Mr. Wells, it is considered superior to all other anæsthetic agents, with the exception that it is very expensive, from the fact that it is difficult to make it well, and still more difficult to preserve, owing to its liability to deterioration by exposure to light and air.

Like chloroform and sulphuric ether, it may be administered on a handkerchief or towel, or with any of the inhalers in general use; but from the peculiarity of being impaired by light and air, and its great volatility, it is best administered by such means as will guard against its being thus affected. Several apparatuses have been devised to accomplish this end, but none have been so generally endorsed as that known as Dr. Junkers', and which is the one preferred by Mr. Wells. Administered by this apparatus, a patient may be kept in a state of perfect unconsciousness throughout a prolonged operation; scarcely any of the vapor escapes into the room; neither the surgeon nor the assistants are affected by it; the light is excluded from the chloromethyl, and the quantity inspired by the patient is wholly within control of the one administering the anæsthetic.

The effects of bichloride of methylene are very similar to those of chloroform, but anæsthesia seems to be much more readily induced by it, and is decidedly more easily recovered from. In fact, its action seems to combine the best properties of chloroform and ether. According to Mr. P. Marshall,* who reported the use of it in five cases before the Medical Society of London, in 1867, the time required to put the patient under its complete influence was from $3\frac{1}{2}$ to 7 min., and the quantity used from 2 to 7 drachms.

In 123 cases in which it was given by Mr. Richard Rendal,† the ages varying from 6 months to 70 years, anæsthesia was produced in 30 seconds in 18 cases; in 60 seconds in 70; in 2 minutes in 25; in 3 minutes in 5; in 5 min. in 3; in 9 min. in 2. Of these 123 cases 50 recovered in 1 min.; 23 recovered in 2 min.; 9 recovered in 3 min.; 28 recovered in 5 min.; 11 recovered in 10 min.

In my own experience, as shown by the records of cases, anæsthesia was invariably induced within 2 min., the longest being 8 min.—one case which had previously resisted taking ether. Recovery was correspondingly quick.

Its effects being much more rapid, from its great volatility, than those of chloroform, anæsthesia is also induced much more quietly, there being, according to the testimony of those who have used it extensively,

a marked absence of mental and muscular excitement or rigidity.

Its effects upon the pulse are, at the outset, to decidedly stimulate and strengthen it; but it soon returns to about its normal state, and never in my experience, as will be shown further on, has fallen much below its normal rapidity or strength. This statement is also supported by the testimony of Mr. Richard Rendal,* who attributes its safety to this stimulating action on the heart, and its rapid elimination, as shown by the rapidity with which patients recover from its effects.

Its effects upon the pulse in the five cases reported by Mr. Marshall, already referred to, were as follows: In three it ranged from 65 to 80; others offered a marked contrast, for in them it ranged from 114 to 120.

In 15 cases of my own, of which a record of the pulse was noted, the following was the lowest the pulse ranged: In three, 75; in five, 80; in three, 84; in two, 88; in one, 96; in one, 98.

Its effects upon the respiration are similar to chloroform. In no case have I seen other than full and quiet inspiration and expiration, and that these functions are properly performed is attested by the generally unaltered color of the skin and lips, which are also in some cases increased to a clear scarlet. This testimony is also supported by that of others, especially Mr. Wells,† who has used it more than 350 times, and who writes: "The patient very seldom becomes pale, sleeps quietly, awakes quietly, and seldom has much bronchial irritation."

The nausea usually following recovery from ether and chloroform is of much less frequency and severity after chloromethyl. In regard to this point Spencer Wells also says: "It is quite true that it has the disadvantage of causing nausea and occasional sickness, but in my experience this is almost always the rule with chloroform, whereas with chloromethyl it is *certainly exceptional*." Mr. Rendal also states that "no sickness or headache follow unless the inhalation has been continued, or a second anæsthetic given to keep up the effects."‡ In his 123 cases, already referred to, vomiting occurred in 15 only; 1 in 8—but in all of these latter it had been continued some time, and some had just been eating. In my own experience, in 31 cases in which I have administered it, nausea or vomiting ensued in but 6, in which latter it was administered for from 20 minutes to one hour, and for severe operations. I have never seen either nausea or headache ensue when it was administered for less than 10 minutes. And Dr. Thomas Bird, of Guy's Hospital, London, writing to me a few weeks ago, says: "As to nauseating effects, if the administration is *prolonged*, the effects are the same as with chloroform, except that the *sickness is not so prolonged*."

As to the question whether chloromethyl is less dangerous than chloroform, or as safe as sulphuric ether, there is some uncertainty.

Mr. Rendal, in his article already referred to, says: "As regards safety, I may add that I have not had a fatal case." And Mr. Wells likewise writes that in over 350 cases in which chloromethyl had been administered for him by Drs. Richardson, Junker, and Day, "in very few of these operations was the insensibility to pain maintained for less than 5 minutes—in a few it was kept up from 45 min. for an hour or more—yet I have never been at all uneasy during the administration or from any subsequent effects fairly referable to it, whereas with chloroform I never felt quite at ease; and although I have never

† Diseases of the Ovaries, page 335.

‡ Loc. cit.

lost a patient during operation. I have three times had to resort to artificial respiration, and I have very often seen patients suffer so much from *chloroform vomiting*, that the result has been imperilled, and in some cases a fatal result has been in a great measure due to this vomiting. When I add that between April, 1870, and March, 1871, I had 32 successive cases of ovariotomy in private practice, without one death, and that the last 24 cases of the fifth hundred, including both hospital and private cases, all did well—every patient having recovered—it must be admitted (as anaesthesia was complete in every case, not one patient having been conscious at any stage of the operation) that the anaesthetic is a good one."

In the 31 cases in which I have administered it, 5 being cases of ovariotomy, and 10 prolonged and severe uterine operations, I have never seen a symptom that made me feel uneasy, and none that so often seem alarming in using chloroform. Indeed, so safe do I consider chloromethyl, when it is carefully given, that I have not hesitated to let others administer in my operations, whom I considered competent to judge of its effects, and Dr. P. B. Porter, who has given it for me eight times, as well as Drs. John C. Jay and F. H. Rankin, have had opportunity to watch its reliable action and evident greater safety over chloroform.

Death, however, has occurred during its administration, and, on looking through the literature of the subject, I have been able to find six cases recorded. In three of these the post-mortems show a large flabby heart; but though it may be proven to be more immediately dangerous than ether, yet the question can plausibly be asked, That if ether has not killed by its immediate anaesthetic effects, how many fatal results *after* operations have been due to its after-effects?

Statistics kindly sent me by my friend Dr. Bird, of Guy's Hospital, give the following as the comparative death-rate of the anaesthetics now used:

Ether, 1 death in	33,000
" and chloroform combined, 1 death in	5,000
Bichloride of methylene, 1 death in	5,000
Chloroform, 0 "	3,000

Having briefly stated the effects and apparent advantages of the chloromethyl, I will briefly report a few of the most prolonged cases of the 31 of anaesthesia induced with it by myself, and thus show all the advantages claimed for it.

CASE I.—Oct. 24th, 1871, I was asked to administer it by Dr. Emil Noeggerath, at the German Hospital, in a case of ovariotomy. Pulse rose at first to 100, but soon fell to 80, at which it continued strong during the *hour and a half* occupied by the operation. Respiration and color natural; but *one ounce* of methylene used. Anaesthesia was induced in 3 minutes, and recovered from in 12, the duration of the latter being due to her exhaustion from the great amount of blood lost.

CASE II.—October 30th, 1871, was again requested by Dr. Noeggerath to give chloromethyl in a case of ovariotomy at the German Hospital. Anaesthesia complete in 2 minutes. Pulse, 105 at first, fell to 84, and continued at that rate, with but slight variations, quite strong. Respiration and color natural; recovery in 3 minutes; no nausea until evening, when vomiting occurred, as had been the case for 2 or 3 days before the operation, as is recorded in Dr. Noeggerath's report of the case to the Obstetrical Society.* Operation lasted three-quarters of an hour. $\frac{1}{2}$ v. methylene used.

CASE III.—Oct. 31st, 1871, gave methylene for Dr.

Noeggerath, at German Hospital, in case of ovario-cerclage vaginalis. Anaesthesia induced in 3 minutes. Pulse at outset rose to 95, but soon fell to 80, and continued strong at that rate during the operation, which lasted 20 minutes. Respiration and color normal. Recovered in less than 2½ minutes. No nausea or headache. $\frac{1}{2}$ iiss. methylene used.

(These three cases will be found in the Transactions of the New York Obstetrical Society, reported in the *American Journal of Obstetrics* for Nov., 1872, and were witnessed by a number of our distinguished physicians.)

CASE IV.—Nov. 12th, 1872, was requested by Dr. T. A. Emmet to give methylene to a patient in the State Woman's Hospital, on whom he was to operate for vesico-vaginal fistula, and who had been exceedingly troublesome in previous attempts at anaesthesia. Was fully anaesthetized in 4½ minutes; made no resistance whatever. Pulse, 105 at first, soon fell to 80, at which it remained strong during the half hour occupied by the operation. Became conscious in less than 2 minutes; no nausea. When asked by Dr. Emmet how she felt, said "finely." But $\frac{1}{2}$ iij. of methylene used. Color and respiration natural.

CASE V.—Nov. 17th, 1872, was requested by Dr. Sims to give methylene to a lady on whom he was to operate for carcinoma uteri. Pulse rose at first to 112, but soon fell to 99 and 96, at which it remained during the hour and a quarter occupied by the operation. Was greatly excited at first, but soon breathed freely, and in 6 minutes was fully anaesthetized. Respiration and color natural. Lost considerable blood; recovered fully in 4 minutes. Some nausea, but nothing vomited. $\frac{1}{2}$ i. methylene used.

CASE VI.—Nov. 20th, 1872, was again invited by Dr. Sims to give methylene to a case he was to operate on for vaginismus. Patient greatly excited and nervous, breathed badly at first. Pulse, 105 at outset, fell in a few minutes to 80, anaesthesia complete in 5½ minutes. Operation lasted 45 minutes; recovered consciousness in 3 minutes; some nausea and slight vomiting. $\frac{1}{2}$ vij. methylene used.

CASE VII.—Nov. 23d, was invited by Dr. Sims to give methylene in a case of amputation of the cervix uteri. Pulse at outset 95, fell to 75, and continued at that rate; anaesthetized in 3 minutes. Color unusually bright and respiration free and full. Operation lasted 50 minutes; recovered consciousness in 2 minutes; very slight retching. $\frac{1}{2}$ iv. methylene used.

CASE VIII.—Nov. 3, 1873, gave chloromethyl to a patient on whom I was to operate for fissure of cervix uteri. Took it well, and in 4 minutes was perfectly anaesthetized. Pulse at first 100, fell to 85, at which it remained strong during the 45 minutes of operation. Respiration and color good. Came out of effects in 3 minutes; no nausea. $\frac{1}{2}$ vij. used.

Beside the above typical cases, which I have selected as those in which the chloromethyl was given for the longest time, I have also the records of others equally convincing as to the advantages of this anaesthetic. I have given it also for Dr. T. G. Thomas in ovariotomy, for Kammerer, Janvrin, and Hanks in other cases, and I am sure they will agree as to its apparent advantages.

The conclusions to be deduced from the foregoing remarks as to this anaesthetic are the following:

It is pleasanter than ether and chloroform in odor.

It is much more rapid in its effects than any other anaesthetic.

It induces no muscular excitement.

Recovery is more rapid and complete than from ether or chloroform.

* Am. Journal of Obstetrics, etc., Nov., 1872.

Nausea and vomiting are rarely induced by it.

Its effect upon the circulation is not so depressing as chloroform, and respiration is much more regular and free.

Like chloroform, its effects are obtained with a small amount, hence it is much more portable.

In fact, I can offer no better praise of its advantages than that by Spencer Wells, who says: "Indeed, the patient has all the advantages of complete anaesthesia, with fewer drawbacks than I have ever obtained by the use of any other anaesthetics."

PERITYPHLITIS—OPERATION — RECOVERY.

By SAMUEL WHITALL, M.D.,

NEW YORK.

On the morning of December 31, 1873, I was called to see Simon H., a boy 8 years of age. He had enjoyed good health until the day preceding my visit, when, about 4 o'clock P.M., he began to vomit, and this symptom continued at intervals during the night. He did not complain of any pain. Considering the indisposition due to gastro-intestinal irritation, caused by an over-indulgence in the luxuries of the holidays, I prescribed a cathartic of calomel and rhubarb, and enjoined a light diet and rest. The following day (Jan. 1, 1874), although in some respects improved, the patient complained of pain in the right leg and lower portion of the abdomen on the right side. Upon examination I found tenderness on pressure, extending from the right iliac fossa to the inner side of the right thigh, near the junction of the middle with the upper third. The absence of tumefaction, of continuous vomiting, and of any markedly localized tenderness, with the open condition of the bowels, inclined me to hope that the symptoms of which the patient complained were muscular in origin, and would yield to rest and anodyne applications.

I did not see the case again until the 7th, when I was called to his sister, who was taken sick in much the same manner as her brother had been, and whose ailment was relieved by a similar course of treatment. During this visit the mother called my attention again to Simon, remarking that he was not doing at all well. Since my last visit his appetite had been generally fair, his bowels not obstinately confined, and urination normal. He, however, complained of pain in the right leg, and could not walk without limping. On the night of the 5th he had vomited three times. He suffered most when touched, or when he attempted to walk.

Upon seeing the child I was struck with the rapid emaciation that had occurred and the anxious expression of countenance. He could not put the right foot to the floor without pain, but stood with the limb slightly flexed and adducted. The pulse was slow but feeble, and the tongue coated with a dirty brownish fur. The pain was now more markedly located in the right iliac region, and there was also great tenderness on pressure. A circumscribed induration could be distinctly felt to the outer side of the caput coli and extending upward a short distance along the outer border of the colon. There had been no vomiting since the 5th; the bowels were sluggish, and there had been loss of appetite for two or three days. My suspicions were now more strongly aroused that I had to deal with a case of perityphlitis. Hoping, however, rather than believing, that the tumefaction might in greater measure, if not entirely, be due to impaction

of faeces, I determined to give a large dose of castor-oil, the operation of which was to be followed by the administration of morphine to the point of producing gentle narcotism. Fluid food ordered; absolute rest enjoined.

8th. The oil operated freely, but without producing any appreciable change in the condition of the parts; the general condition of the patient was, however, more comfortable. The mother thought she noticed a fecal odor in the eructations which occurred during the morning.

10th. No marked improvement since last note. Very little pain when the patient remains quiet, but there is marked tenderness on pressure over the seat of induration, and during the pressure the patient complains of a heavy feeling in the sole of the right foot. Bowels regular, appetite fair, tongue heavily coated. No fluctuation could be detected by careful palpation, nor by rectal touch, neither was there any discoloration or tension of the skin.

Being satisfied that the case was one of perityphlitis, with possible perforation of the appendix vermiformis, I determined to resort to the precautionary operation proposed by Dr. Willard Parker in 1865.

In compliance with my request for consultation, Dr. Herzog was called to see the boy on the 11th. This gentleman confirmed the diagnosis and indorsed the proposed operation. As, however, there appeared to be no immediate danger, we were united in postponing surgical interference until the following day.

12th. Upon consultation, the patient being in about the same condition, it was decided to cut down upon the tumor as proposed.

After the patient was brought under the influence of chloroform by Dr. Herzog—Drs. Hagar, Oberndorfer, and Birmingham being present—I made an incision in the right iliac region, extending from a point about an inch above and within the anterior superior spine of the ilium, downward and inward, toward the symphysis pubis, and parallel with Poupart's ligament. The length of the cut was three inches. The fascia transversalis was exposed by careful dissection, and found to be healthy in appearance, as were also the tissues above it. A careful digital examination revealed a hard immovable tumor, the size of a small orange, immediately beneath the fascia transversalis, with a prolongation extending upward, as previously ascertained. No fluctuation could be felt, nor did any pus escape upon the introduction of an exploring-needle deeply into the mass. In the circumstances, it was deemed advisable not to open the fascia. The upper third of the incision was closed by interrupted sutures, and the remainder of the wound dressed from the bottom with lint. Flax-seed poultices applied.

5 P.M. The patient, four hours after the operation, quite comfortable.

13th. Passed a quiet night; complained of pain at intervals. Pulse, 102; temperature, 99½° F.; tongue heavily coated; considerable pain and tenderness in affected parts; appetite fair, slight nausea, but no vomiting.

14th. Less pain and tenderness; general condition improving. Pulse, 96; temp., 99½° F. Ordered an enema of warm water.

15th. For the past two or three nights, slight perspiration; suppuration moderate, but pus foul-smelling. No movement from bowels, enema to be repeated. Pulse, 102; temp., 99½° F.

16th. Tongue cleaning, patient free from pain; had a slight evacuation from enema. Pulse, 90; temp., 99½° F.

18th. Marked improvement. Pulse, 66; tongue nearly

clean; has had a free movement of the bowels from a dose of castor-oil. The discharge from the wound has been quite profuse for the past two days, but the pus is much less offensive than at first. A careful digital examination of the bottom of the wound, made from day to day, has failed to reveal any fluctuation, though the induration has been gradually subsiding. Very little tumefaction can now be felt.

22d. Patient improving rapidly, wound granulating nicely, water-dressing applied.

27th. The patient can move the right leg freely without causing pain; the wound has nearly healed; no tumor can be felt, nor is there any tenderness, except along the line of the incision.

Feb. 17th. Patient called at my office in a state of perfect health, and has gained rapidly in flesh; he can walk without difficulty, and upon examining the parts not the slightest induration can be felt, and the wound has entirely cicatrized.

Although the mildness of the attack in the beginning warranted the belief that a favorable issue might be expected without surgical interference, and although the sequel tends to strengthen this belief, the history of the above case, in the judgment of the writer, shows at once the advantages and the safety of an operation.

In aggravated cases, in which are present all the physical and rational signs of suppuration, there can be no question as to the propriety of a free incision. The physician who would permit a patient in such circumstances to die without evacuating the pus, would be justly condemned. In those cases, on the contrary, in which there appears to be no urgent need of operating, and in which the prognosis seems to be favorable, it is natural that one should hesitate before endeavoring to assist nature by the aid of the scalpel. This hesitation receives strength from the fact that many cases terminate favorably either in resolution, or by a discharge of the contents of the abscess through some safe channel—through the bowels, the bladder, or the integument.

It is evident that physicians generally are slow to interfere in doubtful cases, for, since Dr. Parker* proposed and successfully performed this operation, few have followed in his footsteps. Scarcely a patient a year has been thus rescued, yet during an equal period, how many lives have been lost by this fatal malady!

Dr. Parker's arguments in favor of operative interference are so clear and so convincing, that it is surprising that any one should refuse to resort to it, or should wish to substitute therefor the tortures of Vienna paste, or the uncertainty and tediousness of aspiration. Could we clearly differentiate the cases which end in resolution from those which go on to the formation of pus; could we ascertain the exact time when suppuration would occur and with equal certainty discover the point of first formation, and then watch from moment to moment the invasion of surrounding parts, we might with safety wait for the critical period to arrive, and with a free and bold incision rescue our patient from impending death. Again, notwithstanding the imminent danger to which the patient is exposed, could it be shown that the proposed operation is *per se* hazardous, hesitation would be justifiable. The truth of Parker's proposition is confirmed, however, by two incontrovertible facts—the great fatality of perityphlitic abscesses on the one hand, and on the other the safety of the operation.

In the present instance I am far from sure that the

operation saved the patient's life; indeed, it is very probable that he would have recovered had no operation been performed. I am more convinced of this by doubts as to whether the indurated mass did not in great measure, if not entirely, disappear by resolution. The pus, although for a couple of days quite offensive, was not discharged in such quantity as one would expect from the breaking down of such a mass. I considered the operation advisable, notwithstanding the absence of any threatening symptoms, for the simple reason that it would be harmless if it should do no good; whereas, without it, a fatal perforation might at any moment occur.

Although I am thus in doubt whether the patient would have survived or not without an operation, I feel quite positive that the incision relieved his pain, improved his general condition, and greatly accelerated his convalescence, while it in no way jeopardized his life.

The favorable termination of this case, and of the one operated on by Dr. Weber,* without disturbing the fascia transversalis, opens the question whether it is better to incise the tumor before evidences of pus are discovered. Dr. Parker has, I believe, in every instance cut into the tumor at once, but the above cases prove that such a course is not always necessary. The fact also that most of the abscesses point externally† tends to confirm this view. The incision through the tissues above the fascia greatly relieves the tension, and invites the pus—if I may use the expression—to pass out through an open door. On the other hand, by cutting through the fascia too soon the peritoneal cavity is more likely to be opened before adhesions have occurred. The danger of hernia, as pointed out by Dr. Weber (*op. cit.*), should also be taken into consideration in deciding the question.

It may be argued that the aspirator does away with the necessity of any incision prior, at least, to the formation of pus, as frequent puncture by this instrument will enable the surgeon to ascertain the precise time when suppuration occurs. When we reflect that matter may begin to form at any point of the indurated mass, and at any moment, we see how frequent and how numerous the punctures must be to insure safety. Few patients would submit to such experimentation. But there is nothing gained by aspiration in cases where suppuration occurs, for in these an incision must eventually be made, and the sooner it is done the better after the first five days (Parker). In the exceptional cases which end in resolution, the aspirator has no advantages over the knife, as the frequent applications necessary would render it equally, if not more, dangerous, while it would not, like the knife, mitigate pain by relieving the tension. The knife, therefore, has the advantage of placing the patient in a condition of safety, without any risk to his life.

In conclusion, I feel warranted in stating, as far as the experience of a single case will admit, that in perityphlitis, where there is any doubt that it will run a favorable course, it is not only justifiable but advisable, at the proper time, to cut down as far at least as the fascia transversalis. If, upon reaching this point, any evidences of pus are found, or if there be great tension, the tumor should be freely incised. If, on the contrary, the tumor be small and circumscribed, and there be no signs of pus, it will be safe to leave the fascia transversalis intact, and watch for an opportunity to lay open the abscess should occasion require.

* N. Y. Med. Journ., Aug. 1871.

Before resorting to surgical interference every other means should, of course, be taken to arrest the morbid process.

607 LEXINGTON AV.

PARALYSIS OF THE HAND AND FORE-ARM CAUSED BY ESMARCH'S BLOODLESS METHOD.

By ROBERT F. WEIR, M.D.,

Surgeon to the Roosevelt and St. Luke's Hospital, New York.

SINCE giving in the RECORD for February 2, a brief account of the results of Esmarch's bloodless operations, a further experience has not only confirmed its usefulness, but also has brought into view a disadvantage which fortunately, however, can easily be obviated.

The occurrence of paralysis, from the pressure of the rubber cord and tubing upon nerve-trunks, was not alluded to by Esmarch, and was brought to my notice in the case of a young man, aged 27, whose left elbow-joint I had excised by the single incision, at the Roosevelt Hospital, in June, 1873, for chronic arthritis, and in whom motion of the forearm on the arm was admirably perfect; yet as there existed sinuses over the ends of the ulna and humerus, leading to bare bone, the patient was etherized, February 13, 1874, and Esmarch's bandage applied, the rubber cord of a diameter of one quarter-inch being, as usual, tightly drawn three times around the limb at the junction of the upper and middle third of the arm, and the proposed operation performed.

The compression was continued about three-quarters of an hour, and the wounds made by enlarging the sinuses were dressed with charpie and gauze bandage.

After the inflammatory reaction of the wound had passed away, it was found that the patient was unable to flex or extend any of the fingers or the hand on the forearm. He complained of numbness in the tips of all his fingers, of the palm and anterior surface of the forearm. The motor paralysis remained unchanged to March 20, when he was kindly seen by Dr. Seguin, but the anesthesia had yielded to hyperesthesia in the dorsum of the fingers, though there was still abolition of tactile sensibility. The examination showed that the lesion was mainly confined to the median nerve. Since that time he has rapidly regained the use of the affected muscles under the use of the galvanic current.

Since recognizing in this way the possibility of such an accident, in the use of Esmarch's method, I have found in the *Medical Times and Gazette*, of January 24, 1874, three cases reported by Langenbeck, where paralysis had occurred in the median nerve after the use of Esmarch's method. Two of the operations performed were for pseudo-arthritis, and one for necrosis; the resulting paralysis in two cases lasted two weeks, and in the other case it had continued three weeks, when he was discharged (cured presumably). Langenbeck, in consequence of this mishap, recommends that instead of using rubber tubing to compress the artery, an independent elastic bandage be used like those employed in forcing the blood out of the limb, and that it be fastened around the limb, after being drawn tightly, by a pin. In this manner the pressure on the nerve is distributed over a broader surface and an injury of it more successfully avoided. The prolongation of the paralysis, in the case narrated above, is probably due to the narrowness and hardness

of the rubber cord employed, as tubing flattens decidedly when applied, and makes thereby a broader pressure.

There is another situation where the same caution should be observed, and that is in the upper part of the leg, where the external peroneal nerve is readily accessible to pressure; though no instance of its paralysis has yet come to my notice.

It is possible also that accidents may result in atheromatous patients, from the increased arterial tension produced by the forced addition of the blood belonging to a limb, to the general circulation. Attention to this source of danger has been called by Mahomed, in the *Medical Times and Gazette* of August 9, 1873, in an article on the use of the sphygmograph in aneurism, in which he has shown that the general arterial tension is much augmented when compression is resorted to in the treatment of aneurism.

No 19 East 32d St., N. Y.

Progress of Medical Science.

THE SULPHIDES IN FURUNCULAR AFFECTIONS.—Mr. Louis Lewis, writing to *The Lancet*, says: "A patient applied to me, suffering from an eruption of boils, which appeared in successive crops, and exuded a thin ichorous pus. I prescribed the sulphide of calcium in small frequently repeated doses (not more than a grain altogether during each day). It was given simply in water, and no other medicine was used. In a few days the pus became creamy and laudable, the inflammation became limited in area, and the boils rapidly died away, no fresh crop appearing.

CHLORAL IN CANCER.—At a recent meeting of the Société Thérapeutique the efficacy of chloral in cancer was pointed out by Dr. C. Paul, who had used it in the shape of suppositories containing fifteen grains. Introduced into the vagina, they had produced sleep during the whole night, in cases where considerable doses of morphia had no anodyne effect, while the nature of the secretions, and especially their color, were favorably modified. Dr. Martineau mentioned a case of recurring cancer of the breast, which had almost reached the thoracic walls and the lung. Pledgets of lint, steeped in a solution of chloral, were introduced. Three days after, the surface had assumed a healthy hue and was granulating kindly, the tumor had vanished and the hemorrhage stopped. Cancer of the uterus had likewise improved, as far as the pain and tumor were concerned, under similar treatment.

BILLROTH'S CASE OF EXTIRPATION OF THE LARYNX; ARTIFICIAL VOCAL APPARATUS.—We recently gave an account of the case in which Professor Billroth, of Vienna, extirpated the larynx, on account of malignant disease. The man on whom the operation was performed was shown at the meeting of the Vienna Medical Society, on February 27th. The apparatus consists essentially of two curved canulae—a tracheal canula and a voice canula; and, for vocal purposes, there is a tongue of silver-plate, capable of producing a deep note. This has been proved by experiment to be preferable to one with a high note, as it allows more space for breathing, and the air can pass more quickly, and more readily produce vibrations in the metallic tongue. By means of this apparatus the patient is enabled to speak well, with a clear sonorous voice; but before he can speak he is obliged to expectorate, to remove the secretion accumulated in the tube. Experiments have been made with a view to forming an apparatus of

elastic membrane, the tone produced by it resembling more closely the human voice than that made by metal; but it has been found to be more difficult to keep it clean, and there is the further objection that its elasticity becomes impaired by use. As a large portion of the epiglottis was also removed, it was thought at first that the patient would not be able to swallow—and, in fact, fluids passed out through the opening that had been made. He learned, however, to push the dorsum of the tongue back when he swallowed, so as to close the opening of the air-passage; and a special apparatus has been devised which acts as an artificial epiglottis. When the patient employed the apparatus the voice was monotonous, but the words could readily be distinguished.

NASO-PHARYNGEAL POLYPUS.—(From the "Vierteljahrsschrift für die praktische Heilkunde," vol. 121, Analecten, p. 32. Translated by E. K. Henschel, M.D.) In connection with a former analogous communication, another very successful case of naso-pharyngeal polypus treated by electrolysis is reported by Dr. Paul Bruns (*Berlin. klin. Wochenschrift*, 1873, No. 32). The patient, 30 years old, since his 16th year suffered from a naso-pharyngeal tumor and imperviousness of the right nostril to the passage of air. At 18 years a tumor the size of a walnut was removed from the pharynx, through the mouth, by means of a scissors. In his 22d year a second operation was undertaken, including the removal of the cartilaginous part of the nasal septum. This operation was likewise unsuccessful. Since then the trouble gradually augmented; respiration, speech, and hearing in the right ear were compromised. In the course of the last three years repeated copious hemorrhages have occurred. On examination (the man being in other respects of vigorous constitution) a voluminous tumor, presenting the typical characteristics of a fibrous polypus, was discovered in the pharynx. It rested apparently, upon the arch of the post-pharyngeal wall, on the right side, filled almost the entire fauces, displacing the palatine arches, and reaching to the base of the uvula.

The tumor was free, of great hardness, the surface smooth and slightly nodular. Rhinoscopic examination showed the lower surface to be partially ulcerated. Besides this the right nostril was filled with mucous polypi. March 12th, the electrolytic treatment was begun, and the electro-puncture executed in the following manner: Strong needles of zinc served as electrodes, and were deeply embedded in the lower part of the tumor. To cover and isolate the needles Eustachian catheters of hard rubber were employed. One needle was introduced through the right nostril, and the other through the mouth, and in this manner nine sittings were held. Six elements of Frommhold's battery were invariably employed, the circuit being first established with one element, and the number of elements being in a like manner reduced to one before the circuit was broken. The time of the sittings varied from 10 to 25 minutes. Two other sittings were also held, at which the negative electrode was inserted into the tumor through the nasal cavity; the positive, armed with a wet sponge, was held in the hand or placed upon the sternum—the number of elements now varying from 10–20, and the time of the sittings being 30 minutes. The attendant phenomena were slight contractions from the establishment and breaking of the current, moderate lancinating pains in the tumor, metallic taste, audible crepitation, due to generation of gas at the points of puncture. Nothing worthy of mention occurred in the intervals between the sittings; not the slightest hemorrhage ever resulted. The first three sit-

tings took place from the 12th to 14th of March, following which a copious secretion of pus and mucous concomitant, with a discharge of small tumor-particles. Rhinoscopic examination showed the under surface of the tumor to be in part ulcerated and in part gangrenous; besides which a marked shrinkage of the tumor was demonstrable. The 4th to 6th sittings were from the 19th to the 21st of March; subsequent to this the treatment was interrupted by intercurrent angina. When the treatment was again resumed, the tumor had diminished to half its former size. The 7th to 11th sittings took place from April 1st to April 7th. Already by this time a progressive decrease in the size of the tumor was perceptible. The patient having returned to his home, presented himself again after four weeks, when it could with certainty be substantiated by examination with finger and mirror that not the slightest trace of the tumor remained. A superficial cicatrizing ulcerated surface was visible on the right side of the pharyngeal arch, close to the base of the nasal septum, corresponding to the point of the former pedicle. The right nasal cavity was occupied by a mucous polypus. It having been removed, not the smallest particle of the tumor existed in the nares or pharynx; the patient was therefore declared entirely cured.

CONCRETIONS OF SAND IN THE INTESTINE.—Laboulbène has found these sandy particles on six different occasions. They have a yellowish or brownish color, and may measure a millimetre in diameter. The surface is uneven and covered with irregular crystals. A careful examination will usually show that the nucleus is of flint, over which are incrustations of organic matter, together with crystals of the triple phosphates. Some of the particles contain vegetable cells, which have not been attacked by the fluids of the intestinal tract.

This sand usually comes from without, and is the result of eating vegetable substances in large quantities, or perhaps the conscious or unconscious use of silicious matters.

The symptoms disappear after free evacuations from the bowels and the use of animal food.—*Ally. Med. Central-Zeitung*, 16, 1874.

INTESTINAL MYCOSIS, AND ITS RELATION TO MALIGNANT PUSTULE.—A number of observations have recently been collected from different sources, and the results tend to show that there is a connection of some sort between intestinal mycosis, or bacterial infection of the intestine, and the disease known as malignant pustule. Wagner has adduced some new cases, and supports the views advanced by Bollinger, Buhl, Waldeyer, and others, who claimed an intimate relation between these two diseases. In one case the intestinal disease was accompanied by a well-marked pustule. In most of the cases the patients had been employed about the skins of animals. Many of them were rope-makers, who cleansed foul horse-hair; one was a sabel-dyer, and another worked in a brush factory. From an anatomical point of view the intestinal lesion was analogous to the pustular, for the bacteria penetrated the diseased villi and extended into the deeper tissues, just as they have been observed to penetrate through the papillæ of the skin in malignant pustule. These parasites, which corresponded to the *Bacillus anthracis* of Cohn, and *Mesobacterium* of Hoffmann, were found in all the layers of the intestine except the peritoneal, in the veins leading from the diseased points, and in one instance in a lymphatic gland. They were also found in hemorrhages of the brain.

Leube and Mueller have published three cases, in which they have arrived at very similar results.

One patient was taken sick after eating diseased

goat's flesh; in the second case the intestinal trouble was accompanied by a decided malignant pustule, and the third was infected by the second, having by accident occupied the bed which the infected person had vacated. The form of bacteria in these latter cases was punctate, while in the others it was thread-like. To test the infectious character of the disease, rabbits were inoculated with the diseased blood and pus, and when large quantities were used the animals became sick and died, and subsequent examination showed that the blood and internal organs were infested with bacteria. Further inoculations were successfully made on other animals. It is interesting to learn that one of the patients recovered. The treatment was carbolic acid internally and externally, and quinine.—*Berl. klin. Woch.*, 7, 1874.

ARTIFICIAL PRODUCTION OF RICKETS AND OSTEOMALACIA.—The fact that lactic acid had been frequently found by chemists in the blood of persons suffering from rickets and osteomalacia, induced Heitzmann to make some experiments on the action of lactic acid upon the bones of living animals.

Selecting a number of dogs and cats, he contrived to have them consume daily a small amount of lactic acid, and at the same time injected it subcutaneously. As early as two weeks after the commencement of the experiment there was swelling of the epiphyses of the long bones, and of the ribs at the attachment of the costal cartilages, accompanied by diarrhoea and loss of flesh. These symptoms increased, and in the following week these bones began to bend in a marked degree. Microscopical examination showed that they presented the same appearance that is seen in the rickets of children. Some of the animals were allowed to recover, and then the experiment was tried a second time. The result was the same. After from four to eleven months of continued use of lactic acid in this way the bones gave the appearances of osteomalacia. The compact substance was very much thinned and the medullary tissue remarkably vascular.

In rabbits and animals living almost exclusively on vegetable food the case was somewhat different. The rabbits died in from three to five months. Guinea-pigs, however, developed marked symptoms of osteomalacia. The conclusions would seem to be, then, that carnivorous animals fed on lactic acid first develop rickets and then osteomalacia. Herbivorous animals, on the other hand, develop osteomalacia without previously having rickets. Finally, osteomalacia and rickets seem to be due to the same general cause, viz.: an excess of lactic acid in the system.—*Berl. klin. Woch.*, 12, 1874.

TRANSFUSION OF LAMB'S BLOOD.—Dr. Hasse, of Nordhausen, has transfused successfully with lamb's blood in 23 cases, dating from May, 1873. The results have been uniformly favorable. Coagulation of blood in the cannula, which has proved a source of difficulty to many, has never prevented him from completing the operation. It will occur when the blood is allowed to stagnate before transfusion; but to avoid such a mishap he compresses the blood-vessels until the transfusion commences. If, however, a single drop of blood escapes before this period, whether it be from the artery of the animal or the vein of the patient, the cannula must at once be removed and replaced by another. The blood pressure in a healthy lamb corresponds to a column of water from four to five feet high. The force of the natural injection is consequently much greater than is usually employed in indirect transfusion, that is, with any of the ordinary injecting syringes. This circumstance may

account for the violent reaction which has often been observed, and would indicate that direct transfusion from the artery of the animal to the artery of the patient might be performed without any intermediate propelling apparatus. Thus far Hasse has only transfused by the former method, viz., from an artery of an animal to one of the peripheral veins of his patient. The success which he has had induces him to recommend this operation, though he states that in exceptional instances the method from artery to artery may be preferable.—*All. Med. Central-Ztg.*, 17, 1874.

NEW METHOD OF CAUTERIZING ULCERS, ETC.—Dr. Thores states that the following method of cauterizing affords the best of results, especially for ulcers, granulations of the cervix, fissure of the anus, etc. This consists in first cauterizing the part with a stick of nitrate of silver, and then immediately touching the white eschar thus produced with a stick of zinc. The eschar at once becomes black and hard; it becomes detached in from 24 to 72 hours, and exposes a clean sore, which generally cicatrizes very promptly.—*Gazz. delle Clin.*, Jan., 1874, and *Gazz. Med. Ital. Prov. Venete*.

EFFECTS OF THE INJECTION OF CHOLESTERINE ON THE BLOOD.—Dr. Müller, after having repeated the experiments which prove that the glycocholate, the taurocholate, and cholate of soda do not, like the alcoholic extract of bile, exert a dissolving action on the blood-corpuscles, injected the bile salts into the veins of dogs. The bile salts thus injected did not produce any cholæmic effects, which is also true when bile is injected, even when the injection is repeated several times. Diarrhoea was the only phenomenon that was observed when a ten-per-cent. solution of the glycocholate of soda was injected into the veins during a period of fourteen days. The injection of four and a half centigrammes of cholesterol, dissolved in glycerine or soapy water, produced, on the contrary, tremors, apathy, difficulty of motion and of respiration, coma, and in one case delirium.—*L'Imparziale*, Jan., 1874.—*Gaz. Med. Ital. Prov. Venete*.

THE TOPICAL USE OF CHLORATE OF POTASH.—Prof. Gosselin thinks the chlorate of potash is much superior to all other local remedies in mercurial stomatitis; it does not, like some others, injure the teeth, but frequently does not act with the promptness desired.

Prof. G. uses a saturated solution of chlorate of potash, and, when there is much pain, he adds laudanum and cherry-laurel water. Pledgets of lint are to be wet with this solution and placed between the gums and the cheek, above and below. The lint is retained several hours, and may be renewed two or three times a day.—*Franc. Méd. — Lo Sperimentale*, March, 1874.

PYÆMIA AND HOSPITALISM.—Pyæmia was the subject of a prolonged discussion at a meeting of the Clinical Society of London on the 23d of last January.

Prescott Hewett read a paper in which he detailed 23 cases of pyæmia that had occurred in his private practice and under the most favoring circumstances as regards residence, attention, and previous health. In the great majority of these patients the attack followed very slight injuries and maladies. The results which the speaker drew were, that hospitalism is neither alone nor chiefly the cause of pyæmia, but that other causes, such as certain atmospheric conditions, can produce the disease in any location whatever. Paget was very decided in expressing his views that pyæmia occurs as frequently in private practice as in hospitals, but owing to the insufficiency of statistics in the former case, we had been unable to draw correct conclusions. He believes that the word "hospitalism" must be

abolished. Other speakers, among whom were Holmes and Hawkins, held similar opinions, which were based upon hospital observations. De Morgan believed that single cases might occur in private practice as well as in hospitals, but he was disposed to think that if several cases occurred in hospitals, after operation, the chances were favorable for the extension of the disease.—*Berl. Klin. Woch.*, 9, 1874.

HYPODERMIC INJECTION OF ERGOTINE IN VARICOCELE.—In a case of varicocele which had existed for a long time, Dr. Bertarelli, of Rome, injected a solution of ergotine under the skin of the scrotum. The solution consisted of ergotine, 1 gramme; water, with a little alcohol, 2 grammes. The patient was ordered to maintain absolute repose and to make local application of cold compresses. The next day the varicosities had disappeared. The success was complete after another injection, which was attended by but slight local reaction.

Dr. Cittaglia had cured another case of varicocele by the same treatment. By the eighteenth day nearly all the varicosities had disappeared; and there was nothing but a slight induration of the corresponding testicle to be observed.—*Ann. di Terapia*, 1874, and *Lo Sperimentale*, March, 1874.

HEART DISEASE FROM SEVERE BODILY WORK.—A number of fatal cases of heart disease have been analyzed by Seitz, of Zurich, and he believes that he has been able to trace the origin of the disease, in a large class of cases, to over-straining the heart. The symptoms given during life were those of severe cardiac affections. The physical signs were weakness of heart action, more or less hypertrophy, friction, and valvular murmurs. The post-mortem appearances were thickening of the walls, dilatation of the cavities, with occasional granular or fatty degeneration of the muscular tissue of the organ. The valves were insufficient, but in other respects normal. In each of these cases the patient referred the origin of his trouble to excessive bodily exertion. The author believes that this disease may give rise to cerebral embolism by the formation of blood-clots in the heart. The termination of such cases is usually fatal, and absolute rest is the most important therapeutical indication.—*Deutsch. Archiv f. klin. Med.*—*Berl. Klin. Woch.*, 7, 1874.

FATAL RESULT OF INJECTION INTO THE VAGINA.—M. Lorain records an interesting observation of an injection into the vagina being followed by death. The patient was a young girl, sixteen years of age, who was suffering from vaginitis, probably of a blenorragic character. After an emollient treatment, consisting of baths and an injection of marsh-mallow, as the surface of the vagina could not be painted with a brush filled with solution of nitrate of silver, M. Lorain gave directions that a weak solution of the nitrate should be injected. This was accordingly done at 10.30 in the morning, with a small syringe, containing scarcely five centigrammes of the fluid. The quantity injected contained only one decigramme (1.54 gr.) of the nitrate, and it was thrown in with due care. Violent pain was immediately experienced. The patient displayed the most marked agitation. Ice was applied over the belly and to the vagina. The temperature of the vagina was 37.8° C., and fell the following day to 37.2°, but vomiting occurred. On the three succeeding days the condition remained unchanged. Stomatitis then supervened, resembling closely that produced by mercury. On the fifth day after the injection death occurred suddenly at 7 p.m. M.

Lorain attributes the accident to the penetration into the peritoneum of a few drops of the pus proceeding from the passages and Fallopian tubes, consequent on the writhings produced by the pain. A post-mortem examination, made by M. Tardieu, showed that there was metritis, with suppuration. The tubes were filled with pus, some of which had flowed into the peritoneal cavity and produced a profuse peritonitis. M. Lorain cites a number of other cases in which a similar accident had happened. He thinks that every woman attacked with vaginitis, accompanied with symptoms which show that the ovaries and Fallopian tubes are affected, is in great danger. The care of the practitioner should be directed to the prevention of all excitement on the part of the patient. Pain should be allayed by opiates and by hypodermic injections.

DESTRUCTION OF ONE OF THE HEMISPHERES OF THE BRAIN—RECOVERY.—M. Porta gives a remarkable case of recovery from this injury. A man aged twenty-eight received a severe blow which fractured his parietal bone, and spilled his brain; he remained in hospital several months in a critical state; the bone exfoliated, and the wound healed, but paralysis of one side remained. On examination one year and a half afterwards, a depression was found covered by cicatricial tissue, into which the finger could be pushed down, and a large void could be found. When the man hung his head the skin became bulged out, apparently with fluid, fluctuating and without pulsation. No intellectual loss was apparent, and paralysis alone followed the injury.—*Med. Press and Circular*.

TREATMENT OF THE ACUTE STATE OF BLENNORRAGIA WITH CANNABIS INDICA AND BENZOIC ACID.—Dr. Lamarte says (*Jour. des Connaissances Méd.*): "During seven years I have in more than sixty cases employed cannabis indica and benzoic acid, when patients have applied to me too late for the abortive method to be resorted to, when the discharge has been purulent and micturition painful, and have never failed of success when I have employed them together. The haschisch alone diminishes the intensity of the disease, but is not always sufficient. Benzoic acid has made some cures, and several half cures, but the two in combination have never failed.

"I advise the tincture of cannabis indica to be used in doses of two grammes, and the benzoic acid in doses of one gramme in a mucilaginous mixture, in twenty-four hours—the usual hygienic measures being followed. For two years I have also used with great success injections of simple water made as often as possible (ten to fifteen times in twenty-four hours), and have always been able to commence with the balsamic and opium treatment within four days at the farthest."

USE OF PEPsin IN THE TREATMENT OF DIPHTHERIA.—Dr. Doughly advises the following formula for softening and dissolving the false membranes of croup and diphtheria: Pepsin, 6 grammes, dilute muriatic acid, 5 drops, distilled water, 100 grammes. To be used by inhalation, in the same way as lactic acid, as advised by Dr. Weber.—*Revista Clinica di Bologna*.

NEW METHOD OF FACILITATING THE DELIVERY OF A HYDROCEPHALIC FETUS.—In *La Tribune Méd.* of April 19th, Dr. Garreau, speaking of this affection, recommends puncture of the arachnoid or subarachnoid space as a means of facilitating the delivery of a hydrocephalic fetus in the case of breech presentations, the puncture being made in the cervical or dorsal region, as the circumstances of the case will admit.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, May 15, 1874.

REORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

A SHORT time since a member of the Medical Society of the County of New York, in making a report as delegate to the State Medical Society, among other things, stated that whenever he attended a meeting of the latter body he was so well satisfied that he always resolved to attend it again, but that each time he was present at the annual gathering of the American Medical Association he declared that it would be the last. It is true that the comparison was not by any means flattering to the attractions of the American Medical Association, but it nevertheless represents a state of professional feeling which has been growing in strength during the past few years. This gentleman was the type of a class who attend meetings to be edified, and who represent the progressive medical mind of the country. It is useless for such of the profession as are still interested in the prosperity of the American Medical Association to shut their eyes to the fact that such men are increasing in numbers every year.

One way to counteract this tendency is to make the meetings interesting and profitable to these men. We have repeatedly pointed out how this may be done, by such an alteration in the plan of the organization as shall effectually exclude profitless discussion in open meeting upon trivial matters of ethics; by raising the standard of delegateship and restricting its privileges to the representative societies only; and by stimulating purely scientific work among the members. We are in favor of devoting the whole time of the meeting to matters of scientific and practical interest to the profession. We care not how this end is attained, and are not wedded to any particular theory as to the particular means to be employed. In fact, everything tending towards the result deserves candid consideration, and the whole matter cannot be discussed too thoroughly.

The new regulation in regard to the different sections will, in our opinion, have an important bearing upon the general question, and deserves a fair trial. The change proposed is a radical one, but all the good that may come of it may be jeopardized at the start by striving to do too much. The intention is, as our readers are aware, to have systematic reports of all the sections made by competent short-hand reporters; these reports to be printed the morning following for the use of the members of the Association. On its face this appears to be a very proper step, and one which promises a vast amount of good to all concerned. If the plan could be carried out successfully, nothing better could be desired. The more the matter is examined, however, the greater seem to be the difficulties in the way of a consummation of the plan.

The making of accurate verbatim reports of these sections is by no means easy. The practice of employing newspaper reporters for this purpose has proved itself utterly impracticable. Although these gentlemen may be experts in their way, they invariably fail in making anything like a faithful account of the proceedings. The main cause for this is a want of knowledge of the technical terms so freely used in all medical discussions, and the natural consequence is a frightful number of gaps to be afterwards supplied either by the speaker himself, or, worse still, left to the discretion of a secretary, who not infrequently has to guess what was meant. We contend that no one can make the reports as they should be made unless he be a competent medical man who is a short-hand writer. If the services of one such can be secured for each section the Committee of Arrangements may well congratulate themselves in taking a great step in the direction of making the meetings interesting and profitable. It would be much better, in case such reporters cannot be engaged, which is altogether likely, to entrust the work to medical men who are able to make good and intelligible reports in the ordinary way. In fact, a verbatim report, except in the larger sections, is by no means necessary to accomplish the real object in view. Our experience teaches us that as a rule they are not worth publishing as such, and seldom, if ever, are readable, unless very liberally pruned of redundancies, irrelevant remarks, and stultifying suggestions. There is always room for the exercise of the widest possible judgment on the part of a competent medical reporter, the chances being that he may have rather too full than too meagre a report.

Another element in the success of these sections is to make the meetings in every respect worthy of the reports to be made. Not every one who may desire to read a paper should be allowed to do so. There should be connected with each of these sections a committee whose business it should be to decide whether or not a paper should be presented. This is one of the reasons why the State Society is so successful in its meetings, why so much valuable material is annually presented

to the members for their consideration and discussion. A proper system could be inaugurated with this end in view, without much trouble, and could not fail to work to the satisfaction of all interested in the special department to which a given section might be devoted.

All papers of any length should be presented in abstract, the shorter the better, and such abstracts should accompany the discussions, the paper in full to be referred to the Committee of Publication.

We have always thought that a good plan would be to refer all papers back to their authors with a recommendation, if worthy, to be published in some one of the medical journals. This would relieve the Committee on Publication of a great deal of labor and responsibility, while it would be serving the profession of the country an excellent turn by laying before it, without the usual delay which attends the appearance of the papers in the expensive volume of Transactions, a quantity of practical material which can be turned to immediate use. Aside from this, there would be an advantage of gaining a much larger and more appreciative audience than if the said paper took the precarious chances of the very limited circulation of the yearly volume. If the reports of the sections are properly prepared, and within the time provided by the new arrangement, they could be used as associated press reports, by all the medical journals throughout the land, and prevent the possibilities of any misrepresentation, which is so foolishly claimed by some gentlemen to be made by some journals which daresay that the Association is not what it should be. Again, the very publication of these proceedings in the journals would be the best kind of stimulus for special efforts by the first minds of the country. This is the reason why most of the best medical societies are so well patronized by the leaders of medical thought, and is oftentimes the only explanation why a continued interest is manifested in the proceedings.

When a delegate or member journeys hundreds of miles to attend a meeting, he has another object in view than mere social entertainment. The expected profit centres itself in the idea of gaining some useful information. If this expectation is not realized, he returns home disappointed, and vows never to attend another meeting if he can help it.

Social reunions are good in their way, but no number of working medical men can be coaxed from their business year after year on the mere promise of collations and excursions. Every Committee of Arrangements should do their utmost to make the meetings a scientific as well as a social success. Not only should they see to it that the sections should be properly conducted, but that the general meetings should be occupied for the most part in scientific business. A special effort in the direction of making these attractive in this respect would be to have an address on some of the medical topics of the day, by some of the representative men from different parts of the country.

Prof. Gross, of Philadelphia, struck the key-note in regard to this point, when he suggested the delivery of addresses on medicine, surgery and obstetrics, to occupy the time taken up by reports of medical literature, medical education, and similar topics. Perhaps the most memorable meeting of the Association which we ever attended was one in which Brown-Séquard gave a lecture in open session upon the diseases of the nervous system. Similar lectures have been delivered by other distinguished gentlemen since that time, and the success has been such that it needs no special argument in their favor. Care, however, should be taken by the Committee of Arrangements to have such lectures thoroughly representative, original, suggestive, and practical—something to which each member in attendance can look back with satisfaction, something which may seem to encourage him to work when he gets home, something which may give him new ideas of the treatment of disease.

The Committee of Arrangements at Detroit are so anxious to make the meeting a success, that we have thought it not out of place to offer some suggestions which may have a tendency to that end. We heartily sympathize with them, and would be glad to see the Association once more on its feet, to know that it had straightened itself up to the work expected of it; and so long as it has a spark of vitality left in it we shall not tire in doing our best to uphold its hands. At the same time that we are happy to do this, it is nevertheless our duty to state what has long been our conviction, that unless some change in its organization is effected, some departure is made from the old routine of sluggish indifference to the interests and wishes of the profession of the United States, its death is inevitable.

While urging attention to the scientific business, we do not forget that the Association have some legislative functions to perform. It is not necessary that such business should be transacted in full session. In all matters connected with medical ethics there are always a great many details to master before there can be a proper understanding of the merits of any case. We are in favor of having all the pros and cons discussed, but the only way that it can be done satisfactorily and with the greatest economy of time to all concerned, is by a large and representative committee, whose report should be accepted or referred back, as the circumstances of a general vote might determine.

Our most successful societies are managed in this way, and the harmonious workings of the system give no chance for improvement. The New York Academy of Medicine nearly ruined itself by the discussion of questions of ethics in open session—in fact, the time which should have been devoted to other and weightier matters was so completely occupied by the ventilation of the opinions on ethics of certain members who could have an opinion on no other subject, that the best men absented themselves. Finally, the much-needed reorganization was effected, and the

purely business element was confided to a well-chosen council with almost absolute power. At once the character of the meetings changed, and the way was opened for scientific work proper. And after all, a council can settle vexed questions better than members who may chance to be present at any meeting at which a question may be brought up. A council has special facilities for examining matters of a more or less private character, which could not be done in a promiscuous meeting. It is apt to take pride in having its report representative of the general sentiment of the profession; and is inclined to give digested reasons for the opinions entertained. The merits of the case must necessarily be studied in all its relations, a healthy conservatism pervades, as a rule, the recommendations made, and sound judgment tempers the suggestions offered. Again, there would not be any likelihood of taking extreme grounds either way, such as in open meeting would be inevitable where interested parties are generally the only disputants. As we have so often said before, we believe that the committee-plan is the only one which shall effectually prevent the family quarrels so frequent of late in the general sessions. We are happy to be officially informed of the fact that such a council has been created, and that the plan which we have so persistently suggested for the past few years, has at length been adopted. At the coming session there will doubtless be an opportunity to test its merits.

NURSING AS A SCIENCE.

As there is no unmixed good, so we seldom or never find unmixed evil. While the nation is groaning under the mischiefs, the demoralization, consequent upon our late war, we may, by looking closely, discover also many benefits. Not the least of these is the development of new sources of power, and of new principles in the care of the sick and of the wounded. It has opened a broad field of action for women, ladies, which perhaps they would never have entered in any other way.

The idea of war is terrible, and there is something unphilosophical in maiming men and blowing them to pieces, and then setting earnestly to work to put them together again, because the patchwork never looks as well as the original pattern. Still, if men will fight, we may rejoice that the means of help are at hand for those who are so happy as to survive. In this, ours is distinguished from ancient warfare, in which, so far as we can learn, the wounded were left to die.

In our camps the nursing abilities of women were developed. Just as they had begun to cry out for a wider field of action, and as the Governor of one of the States had characterized a large proportion of them as "anxious and aimless," they found this new outlet for their activities, and so happy were men to receive their "handy" and gracious assistance in camp

and hospital, that they never stopped to inquire whether the thing were according to rule or not.

The tale has been told often enough; and having learned what she can do, woman is too wise to retire again to needle and novel and her "sphere," unless the same be expanded enough to allow her a place to work. There are those who will study medicine, who love it and choose to follow it, and who shall gainsay them? But it remains a fact, that few if any women can bear the wear and tear of ordinary medical practice, the night-work, the irregular hours, and the frequent demands upon physical strength.

There are branches of the profession which they can pursue, but we hope never to see them "general practitioners," because there is a more important place for them, and one in which a medical education will be equally valuable. They can be nurses, not mere hirelings, but intelligent, cultivated nurses, with human lives in their hands.

We know there are many diseases in which treatment is nothing, and nursing is everything; where the skilled nurse is really more valuable than the doctor, if you can have but one. We all know the misery of seeing a patient slipping through our fingers, in spite of all our care and skill, through neglect or ignorant interference. We all know what an angel of light is a good and intelligent nurse to us in our time of need. But at present this is in a great degree a matter of chance. If, like "reading and writing," nursing comes by nature, all goes well; there are a favored few, and the rest of the world suffers. Ignorance, and neglect, and queer superstitions carry the day.

Our want is educated nurses. We have made and are making some faint attempts to supply this want—we are beginning to have training schools. In other countries, as in Russia, these schools are established and controlled by the government, and may require and insist upon a long and thorough course of instruction. Here, where all is voluntary, we have many difficulties to contend with, the want of money, and the great national want, *the want of time*.

We are in too much of a hurry, to learn anything well. Still we may hope in time to gain in this regard—and we will do as well as we can.

Books may help us. Nursing is a science, best learned by long and careful training. Failing in that, the experience of one who has had that training may be the best guide we can command. Miss Florence S. Lees,* an English lady, has written a book, which she dedicates to Miss Nightingale, in which she gives the results of her experience in French, German, and English hospitals, in time of peace and war.

Sir Henry Acland writes an introductory chapter, the key-note of which is nursing is the medical work

* Hand book for Hospital Sisters. By Florence S. Lees, Superintendent of the Ambulance of H. L. & L. H. the Crown Princesses of Germany and Prussia, for the wounded in the late French and German war. Edited by Henry W. Acland, M.D., F.R.S. W. Isbister & Co., 56 Ludgate Hill, London, 1874.

of women. Miss Lees dwells upon the importance of thorough training, understanding practically every part of the work, from the least to the greatest; the qualifications of a nurse, for not every one is fitted for the great trust; all the details of hospital management.

Then follow—Ward Duties; Bedding and Bed-making; Medicines, Poultices; Ward-Dressing; Leeches, Cupping, Blistering, Bandaging and Surgical Work; Fevers, Antiseptics and Disinfectants.

Also general directions for preparing food for the sick—one of the most important departments. All of us know the miseries of having a patient starved, or more generally stuffed with improper food.

"Doctor, he'll die, if he don't eat."

"Madam, he'll die, if he can't digest."

Our poor sick fellows in the old days in camp could tell what it was, when men brought them a plate of fat pork, or hard bread and a sodden potato, for a fevered palate.

Medicine is very well, but, dare we say it, the nursing and the feeding are responsible for the patient's recovery. Medicine may drive out the enemy, but it yet remains to repair and fortify the citadel. Some day the people will find this out, and help us with money, which, with our profession, does not so much abound.

In the good time coming we shall have pavilion and barrack hospitals, less imposing and *less costly*, but better for the patients; and thorough training schools, where nursing as a science shall be taught, and practised. Until then such a book as this of Miss Lees' will be most valuable, and when carefully studied and often referred to, will help the efficient, while it will, we trust, discourage the ignorant and inefficient from undertaking work which is too high for them.

It is only when we read how many things are to be learned, that we appreciate the vast importance of a thorough professional education in a nurse.

Reviews and Notices of Books.

A DICTIONARY OF MEDICAL SCIENCE, containing a concise explanation of the various subjects and terms of Anatomy, Physiology, Pathology, Hygiene, Therapeutics, Medical Chemistry, Pharmacology, Pharmacy, Surgery, Obstetrics, Medical Jurisprudence, and Dentistry; Notices of Climate, Mineral Waters; Formulae for Official, Empirical, and Dietetic Preparations, with the Accentuation and Etymology of the Terms, and the French and other Synonyms. By ROBERT DUNGLISON, M.D., LL.D., late Prof. Institutes of Med. and Med. Jurisprudence, Jeff. Med. Coll., Phila. A new edition, enlarged and thoroughly revised by RICHARD J. DUNGLISON, M.D. Phila.: H. C. Lea. 1874. 8vo, pp. 1131.

THERE is probably no medical work, a new edition of which has been more earnestly looked for than Dunglison's Medical Dictionary, none for which a revision and amplification was more a necessity. For forty years it has maintained its place as the best Dictionary

of Medical Science that has during that time been published; in fact, few scientific medical works have enjoyed a reputation equal to it. The edition before us was commenced by the lamented author, and has been completed by his son, whose talent in this direction is a cause for congratulation to himself and to the profession at large. We have examined the work in its different parts, as much, in fact, as the duties of a conscientious reviewer demand, and as the result of our investigation we are pleased to record our gratification at the success of the editor in his new rôle. We can say nothing better of him than that he worthily occupies the position of his father, and has proved himself the capable interpreter of his father's designs. When the plan of a work is so generally known to medical scholars, and its great success so thoroughly admitted, it is generally safe to speak of it in terms of commendation—to find fault with it is, however, no easy task. This part of the critic confines itself to the labor of analyzing, almost word for word, a labor-task almost equal to actually editing the book. We have, however, done the best we could to find any inaccuracies and avoidable omissions, but have failed to discover any. On the contrary, the more we have examined the work the greater has been our surprise that it contained so much useful information.

Having said this much, we come to notice the peculiarities of the present edition in the shape of additions and improvements upon its predecessors. The large number of new words introduced into our medical vocabulary has naturally necessitated much addition to the size of the work, which necessity has been met in part by the enlargement of the size of the page. The editor states that more than six thousand subjects and terms not embraced in the last edition are included in this. A very desirable improvement also consists in the use of heavy type for all the terms, and small capitals for synonyms and subordinate words. Under the subject of Weights and Measures is an explanation of the relative values of the quantities employed in the official formulæ of this country and Great Britain, which latter, as is now well known, blends the formulæ of the Dublin, Edinburgh, and London Pharmacopœias.

The most that we can say for the present edition is that it is fully up to the requirements of the times, and fully sustains the enviable reputation which this Dictionary has always maintained of being incomparably the best of its kind in any language.

A HANDBOOK OF THE THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., B.Sc., M.R.C.P., Fellow of Univ. College, Philadelphia: Lindsay & Blakiston. 1874. 8vo, pp. 1040.

DR. ROBERTS' book is avowedly nothing more than a compilation intended as a comprehensive guide in the study of medicine, to the medical student and young practitioner more particularly. We are not aware that the author has given us anything original either in subject-matter or plan, but he has, nevertheless, performed the work he set out for himself at the beginning in a very thorough and satisfactory manner. As a gentleman who is evidently a practised hand in preparing medical students for examination, he has become thoroughly acquainted with their wants, and has cultivated a faculty of imparting his information in an intelligible, terse, and straightforward manner. As a work its comprehensiveness entitles it to be called a model text-book, rather than a mere manual. It is unnecessary to speak of the different sections of the treatise any more than to say that they are exceedingly well worked up, giving proof of extensive knowledge, a well-balanced practical mind,

and an honest regard for the plain unvarnished truth. The book is well printed and well got up.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 2, 1874.

DR. AUSTIN FLINT, President, in the Chair.

TREATMENT OF HEMIPLEGIA.

THE paper for the evening was read by Dr. Geo. M. Beard, upon "Practical Points relating to the Treatment of Hemiplegia."

The leading features of the paper were as follows: Treatment should be begun early. In general (with regard to electric treatment) too strong currents have been used, and have been continued too long. Electricity is a sedative as well as stimulant.

There is no need of producing another lesion of the brain by employing electricity. A galvanic current may be sent through the seat of the disease in the muscles, and local applications may be made to the muscles when the effects of the lesions are manifested. The spinal cord becomes degenerated from lack of use, shown by stiffness of the muscles, etc.; hence the electric treatment should also be directed to the spinal cord. This is an important point. Recent experiments have shown that a galvanic current can be sent through the part in the brain where the lesion is supposed to exist. Outside of theory, the following are practical considerations of much importance.

1. Enlisting the will of the patient to assist in the moving of the muscles. Get the patient to throw all the cerebral force into the movement of a hand or foot. The rapidity of the recovery depends very much upon the organic will of the patient. The medical man can accomplish very much more by urging that will into resolute action.

2. Relax the muscles at the time the application of the current is made. This is accomplished by giving the muscles artificial support, by an assistant's hand or otherwise, while the current is being applied. A contraction can be obtained when the muscles are supported or placed in a relaxed condition, when it cannot otherwise be obtained. It is very beneficial to maintain the artificial support throughout the entire course of treatment. The apparatus of Dr. Van Bibber, or the rubber muscle of Dr. Sayre, may be employed for this purpose with advantage.

He had found some difficulty in making *easy* attachments for the rubber muscle. It is desirable to have something which the patient can have adjusted, and can wear with comfort.

3. Free application of dry or moist heat to the muscles and joints.

Localized dry heat can be conveniently applied by means of clay tubes, which can be made of any shape or size desirable. The tubes can be heated in an oven, covered with a cloth when removed, and then the arm or leg can be inserted and permitted to remain for a number of hours. This should be repeated once or twice a day.

The use of this means is beneficial, from the fact that it improves muscular nutrition and the nutrition of the joints.

It is especially beneficial in the treatment of the small muscles of the hand.

5. Passive movements, especially of the shoulder-joint.

This should be begun early and done very much more thoroughly than is customary in a majority of cases.

5. *Massage.* This can be applied to individual muscles.

When this means is alone employed it is not productive of very wonderful results. Indeed, the same, to a considerable extent, may be said of all these measures. All these measures may be adopted at once. Make one strong pull all together. It is like the farmer's pulling out a stump by attaching many horses at once, and not by hitching up one at a time, working him until he is exhausted, and then attaching another.

6. Use of nerve and brain food.

This embraces cod-liver oil, phosphorus, etc., etc. Strychnia, hypodermically used, is also very serviceable.

Dr. Andrews, of the State Lunatic Asylum at Utica, has given a formula for preparing cod-liver oil which disguises its terrible taste, and places a valuable agent at our command in almost every case.

Dr. Squibb has remarked to me that he regarded it as the best formula he had ever seen. The chief objection to it is the fact that it is difficult to get the druggists to prepare it in the proper manner, because it requires so much time. When thoroughly prepared it will keep well for a long while.

FORMULA.

Yolk of eggs.....	No. iv.
Glycerine.....	i.
Cod-liver oil.....	iv.
Phosphoric acid dilute.....	ii.
S'erry wine.....	ii.
Essence of almonds.....	i.

The eggs and glycerine are first to be carefully triturated in a mortar, and while the trituration is continued add the oil, drop by drop. When this is done, the acid, wine, and essence may be added. The above is not the precise formula used at the Asylum, but it is essentially the same. The manner of making the emulsion is the important feature. The amount of phosphorus can be varied to suit different cases, or other remedies may be added, such as arsenic, etc.

A number of cases were then cited, illustrative of the benefits which may be obtained by placing in practice the items of treatment mentioned.

Three things are noticeable relative to prognosis:

1. There is a tendency in a majority of cases, which are not speedily fatal, to slow but spontaneous recovery up to a certain point. Cases, however, which are properly treated will improve much more rapidly than if left to themselves.

2. In those cases where spontaneous recovery is evident, and will be carried on to a certain point, treatment should be carried along side by side with the spontaneous improvement, and not deferred until spontaneous improvement has done its work.

3. Prognosis in cases complicated with hysterical and nervous symptoms, is better than in cases which are not so complicated. A hysterical, nervous temperament seems to antagonize the effects of the disease. The nervous are easy to make sick and easy to make well, while the lymphatic are hard to make sick and hard to make well.

Dr. J. J. MASON remarked that he could not refrain from criticising one portion of the paper just read, and that was with reference to the passage of a continuous galvanic current through the brain-substance. It is

perhaps a measure worth trying, but for a measure to be indicated as properly belonging to measures to be adopted, it must have been tried in a sufficient number of cases, and have been followed by results which can be traced directly to the action of the remedy.

Benedict of Vienna, Gross of Paris, and Althaus, were mentioned among the advocates of the measure, but none of them have been able to report any cases of success, except perhaps it may be in some hysterical women. From his own observation, but chiefly from study, he could not see any indication for resorting to the measure at all.

DR. NETTEL remarked that when there was apoplexy the cause is not a local but a general condition of the walls of the blood-vessels. This condition must be taken into consideration while treatment is being adopted. There are certain cases where, upon post-mortem examination, the gross appearances of the brain remain unchanged, but the microscopic lesions will be found to be important, such as are connected with the perivascular spaces, etc. As a secondary effect of such lesions, there may be affection of the nervous elements and consequent atrophy, etc. It is further known that such lesions are produced by irregularities in the circulation, and these again are produced by affections of the vaso-motor system. It is also important to take these conditions into account in the treatment. Regards the use of stimulants as bad. One of the best remedies, from his own experience, is the galvanic current passed through the brain and sympathetic. It must be used, however, with the greatest care, if injury would be avoided. The current should be very mild. Arsenic is also a very important remedy. It has the power of preventing such congestions. Administer from one to three drops of Fowler's solution once or twice a day, and continue it for a month or more.

It is important never to forget that the affection of the brain calls forth a secondary affection of the spinal cord; hence the spinal cord should receive treatment at the same time, in order to prevent, as much as possible, those secondary degenerations.

DR. VAN BIBBER cited a case in which the improvement which had taken place as the result of placing the muscles in a state of relaxation, was much greater than could reasonably have been expected without the adoption of this measure. He also cited a case of *potosis* in which the lid was raised by a thin piece of rubber band attached to it by means of court-plaster, and then covered with collodion, and the other extremity secured to the forehead in the same manner. The benefit, which had accrued since the application of this simple device, had been marked.

THE NEW YORK NEUROLOGICAL SOCIETY.

A STATED meeting of this Society was held at the College of Physicians and Surgeons, on Monday evening, the 4th inst., when the President, Dr. William A. Hammond, delivered an inaugural address on "The Effects of Alcohol upon the Nervous System."

The paper was quite extensive, and embraced the results of a series of experiments made by the author. In the course of the reading, test-tubes were exhibited which contained the products from distillation of aqueous extracts of the brain, spinal cord, large nerves, and blood, respectively, of a rabbit, which had, for ten days preceding its death, been obliged to ingest considerable quantities of alcohol, and which had taken its last dose six hours previous to being killed. Ex-

amination with a test solution of bichromate of potash with sulphuric acid, showed alcohol to be present in all excepting the last, and the distillates from the brain and spinal cord contained a sufficiently large amount of alcohol to enable it to be detected by the sense of smell.

Speaking of the general effects of alcohol upon the system, Dr. Hammond recited experiments made upon himself, in 1856, in which he tried, first, the use of alcohol, together with an allowance of food sufficient in itself to sustain the body; second, with a quantity of food which fell short of the amount required to nourish the system; and third, a quantity of food greatly in excess of what the system could consume. The results were to show that in the first series the use of alcohol deranged the functions of the economy; in the second, it prevented a loss of weight, which would otherwise have taken place, and seemed to take the place of a certain proportion of food; and in the third, it acted as a poison, persistence in the use of which would have terminated seriously. The Doctor mentioned the theory which, to his mind, came nearer to explaining the healthful action of alcohol in the economy than any other, viz., that in certain states of the system alcohol seems to combine with some of the earliest forms of substances which are the result of retrograde metamorphosis, forming compounds which may again be used in the nutrition of tissues, and which just so far take the place of food, introduced from without.

He recited a long list of the diseases and conditions which depend upon the wrong use of alcohol, among which the different forms of sclerosis played an important part, and referred particularly to the acute and chronic forms of alcoholism; saying that the former should be distinguished as being divisible into two varieties: one, dependent upon the presence of alcohol in the circulation and nerve-tissues, being best treated by eliminating remedies, such as diuretics, diaphoretics, etc., alcohol and opium being decidedly contraindicated; while a second condition, being one of exhaustion following the effects of alcohol poisoning, could best be treated by just the remedies which would be inadmissible in the first variety.

For those who were the victims of chronic alcoholic intoxication, and had lost the power of controlling their appetites, he advocated *vigorous* restraint; as complete as that exercised over lunatics, with the addition of legal penalties for acts of infringement upon the laws of society. He referred to the examinations made and recorded by Dr. J. C. Peters, in 1843, with regard to the hardened condition of the brains of those who had died of chronic alcoholism; and expressed the hope that the question of the action of alcohol upon the nervous system would receive the earnest attention of the members of the Society.

Remarks were made by Doctors Lente, Willard Parker, J. C. Peters, Clymer, and others, and it was resolved to continue the discussion of the paper at some future meeting of the Society.

The attendance was very large, numbers of clergymen, lawyers, and other than medical men being present; and Dr. Meredith Clymer, President of the Society of Neurology and Electrology, occupied a seat on the platform.

THE MEDICAL STAFF of the New York Foundling Asylum consists of Doctors J. B. Reynolds, J. Lewis Smith, Chas. C. Lee, and Joseph O'Dwyer. There is no resident staff, the directions of the Visiting Physicians being carried out under the supervision of the Sisters of Charity.

MEDICAL SOCIETY OF THE EASTERN DISPENSARY, N. Y.

DR. R. J. O'SULLIVAN, PRESIDENT, in the Chair.

INCISED WOUND OF TENDO-ACHILLIS, WITH COMPLETE DIVISION.

DR. GEORGE H. MITCHELL introduced the following case, accompanied by sketches illustrative of the lesions:

The patient, Jos. E. R., age fifty, publisher, 59 Beekman street, City, was present by invitation. On Friday evening, January 9th, while bathing at French's Hotel, thrust his right foot through the porcelain basin of a stationary washstand, and the sharp edge cut through the skin, fascia and tendon, followed by copious arterial hemorrhage. This latter was speedily controlled by torsion and styptics, and the lower cut end was observed standing out in bold relief, the surrounding skin retracted, and to the touch feeling like a painter's brush, the interspace between the cut extremities being about three inches.

By a splint firmly fixed on anterior aspect of the leg and below the knee, the foot was extended. Strips of adhesive plaster were then applied over the calf, crossing like a pair of suspenders, and secured under the plantar arch; the edges of the wound brought together with two stitches, the limb placed on an inclined plane, and the whole treatment continued thus, and completed with application of ice-cold water dressings.

The fifth day the patient rises on a cane, and the seventh, in a shoe with high counter, an initial bandage and woollen sock, attends to business and other duties, in his carriage, and is to-day able to walk with the help of a cane short distances.

The gastrocnemius and soleus, parent muscles of this tendon, are noticeably quiet, any effort on their part in the lifting of the heel, even poising the weight of the body on the injured foot, being instantly followed by the patient quickly tottering to fall.

Queries.—On this thirteenth day after the injury, is this good result exceptional? and what would be the effect of bringing the cut ends together by silver sutures?

DR. O'SULLIVAN considers this case remarkable in result, also rare in occurrence; would have prognosed a year.

DR. ABBOTT saw a case of a woman in whom the tendon was cut by a broken edge of a chamber vessel; locomotion in about twelve months. This result is remarkable.

DR. SKIFF considers the suture has not a precedent. Had a case of a lad 13 years of age, cut by a mower; was under observation about a year, and at the end of that time walked tolerably well. A second case of an old lady, frightened, stepping hastily from her carriage, ruptured this tendon; saw her about a year afterwards, and she walked round pretty well.

DR. GARRISH thinks the suture thus employed should be silver, or other metal. The present result excellent.

DR. MULREANY never had a case of injury to tendo-achillis of like character. Heard of a case, while in Ireland, of a man cutting the tendon with a shearing-hook, while harvesting seaweed. No other assistance at hand, a shoemaker sewed up the wound; in a few months the one foot was apparently as strong as the other; considers twelve months remarkable to secure good result.

New Instruments.

A NEW TORSION FORCEPS.

SOME two years ago Professor Post presented at the Pathological Society of this city a forceps invented by Dr. Hewson, of Philadelphia, for arrest of hemorrhage by torsion; it being so arranged that one portion of the forceps steadied the vessel, while another gave it the necessary rotary motions. Mr. Stohmann, of the firm of Geo. Tiemann & Co., has since constructed an instrument on the same principle, but differing somewhat from the forceps of Dr. Hewson, from which he received the idea. As will be seen by the cut, a blunt-nosed artery forceps has its blades closed upon the vessels by means of a slide, which is controlled by a rod passing through the shaft and into the handle, where it terminates in a button. Sliding upon the shaft of the artery forceps is a "carrier," which supports the pivot of another pair of forceps. The blades of the latter are curved so as to grasp the vessel beyond the point seized by the first pair, and catchers are attached to the handles so that the forceps can be held fast without the help of the operator.

In using the instrument the forceps last described is opened, and the artery forceps projected between and beyond its blades; the vessel is seized, drawn from its sheath; the second forceps is then pushed forward and made to grasp the vessel, and then, without any risk of the relation of the two forceps to one another being disturbed, the first pair can be rotated, and the twisting of that portion of the vessel between it and the retaining forceps accomplished.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 19, 1874, to May 4, 1874.

BAILEY, J. C., Surgeon.—Assigned to duty at Frankfort, Ky. S. O. 61, Department of the South, April 20, 1874.

McCLELLAN, ELY, Assistant Surgeon.—To carry out provisions of joint resolution of Congress, approved March 25, 1874, on the recommendation of the Surgeon-General, detailed to inquire into and report upon the causes of epidemic cholera. S. O. 85, A. G. O., April 18, 1874; and by S. O. 67, Department of the South, April 20, 1874, relieved from duty at the Post of Lebanon, Ky.

GARDNER, WM. H., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Union, N. M. S. O. 82, District of New Mexico, April 14, 1874.

MIDDLETON, P., Assistant Surgeon.—When relieved by Surgeon Baily, to comply with S. O. 78, c. s., War Department. S. O. 61, c. s., Department of the South.

LIPPINCOTT, H., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Whipple, A. T. S. O. 85, Department of Arizona, April 9, 1874.

DEWITT, CALVIN, Assistant Surgeon.—Assigned to duty at Humboldt, Tenn. S. O. 61, c. s., Department of the South.

GIRARD, A. C., Assistant Surgeon.—Relieved from duty in the Department of the South, and assigned to duty at the U. S. Military Academy, West Point, N. Y.; so much of S. O. 79, c. s., A. G. O., as grants him four months' sick leave having been revoked. S. O. 90, A. G. O., April 25, 1874.

GIRARD, J. B., Assistant Surgeon.—Assigned to duty as Post Surgeon at Camp Lowell, A. T. S. O. 35, c. s., Department of Arizona.

POPE, B. F., Assistant Surgeon.—When relieved by Assistant Surgeon DeWitt, to comply with S. O. 78, c. s., A. G. O. S. O. 61, c. s., Department of the South.

FITZGERALD, J. A., Assistant Surgeon.—Relieved from duty at the U. S. Military Academy, and to report in the Commanding Officer, Department of the Columbia, for assignment to duty. S. O. 90, c. s., A. G. O.

MOFFAT, P., Assistant Surgeon.—Assigned to duty at Fort Garland, C. T. S. O. 32, c. s., District of New Mexico.

Medical Items and News.

AMERICAN MEDICAL ASSOCIATION.—The undersigned has been appointed a committee to procure reduced fares for those attending the meeting of the American Medical Association. The fare from New York to Detroit is now \$16.25. If a sufficient number of gentlemen participate, it is hoped a reduction may be procured of probably \$22, to Detroit and return, by Erie and Great Western R. R., via Niagara Falls. Palace and sleeping cars extra. The trip is made in about 25 hours, without change of cars. Gentlemen who wish to avail themselves of the above privileges will please notify the undersigned at once how many tickets they desire, in order to enable him to make the most favorable terms. An answer, with particulars and results, will be forwarded in proper time.

ROBERT NEWMAN, M.D.

145 West 47th St., New York.

DR. F. MARKOE WRIGHT.—At the annual meeting of the District Medical Society of Bergen County, N. J., the following preamble and resolutions were offered by the retiring President, Dr. Currie, and unanimously adopted:

Whereas, It has pleased Almighty God to remove from this world our President and friend, F. Markoe Wright, M.D.; while bowing humbly to this dispensation of an All-wise Providence, we, who shared his toils and witnessed his devotion to the exalted duties of his self-sacrificing profession, may be permitted to give some public expression to the feelings which so sad an event cannot fail to excite; therefore,

Resolved, That in the death of Dr. Wright, this Society has lost an able and prominent member, the community a highly esteemed and gentlemanly physician, and a devout Christian.

Resolved, That during his professional career he distinguished himself by a blameless life, an honorable character, genial sympathies, reverence for truth, and respect for the rights of others; and in his jealous watchfulness over professional purity and honor, he left us an example worthy of imitation.

Resolved, That to his bereaved relations we tender our heartfelt sympathy, invoking for them Heaven's choicest consolations, and assuring them that we shall ever cherish in our hearts pleasant memories of his life.

JOHN H. GRISCOM, M.D., who died suddenly on the morning of Tuesday, the 28th ultimo, was born Aug. 14, 1809, in this city, and was the son of John Griscom, LL.D., who was well known years ago as Professor of Chemistry in Rutgers Medical College, New Jersey. Dr. Griscom studied medicine with Prof. J. D. Goodman and Valentine Mott, at Rutgers Medical College, but was graduated from the University of Pennsylvania in 1832. The following year he was appointed Assistant-Physician of the New York Dispensary, of which he became Physician in 1834. From 1836 to 1840 he was Professor of Chemistry in the New York College of Pharmacy, and in 1842 he was appointed City Inspector, which position he held one year, when he became Visiting-Physician of New York Hospital, in which service he continued until a few years since. From 1848 to 1851 he was General Agent of the Commissioners of Emigration. Dr. Griscom was the author of a large number of medical books and essays, the most prominent of which were the following: "Animal Mechanism and Physiology," "The Sanitary Condition of the Laboring Classes of New York," and "The Uses and Abuses of Air and the Means of the Ventilation of Buildings." He was a strict adherent of the Society of Friends. During the

past few years he has been unable to practise, but in his long public life he gained an excellent professional reputation, and made many friends.

ARCHIVES DE TOCOLOGIE is the name of a new monthly started in Paris, and devoted to the diseases of women and infants. It is published by Professor Depaul, with the assistance of Doctors Bailly, Bernutz, Blot, Charpentier, Guéniot, Hervieux, and of Sayre, Editorial Secretary. Each number consists of sixty-four pages, and the subscription price is, for Paris, eighteen francs.

A NEW GERMAN JOURNAL.—Another weekly periodical is about to be added to the list of excellent publications of this sort in Germany. It is to be called the *Centralblatt für Chirurgie*. It is to be published at Leipzig, under the editorship of Drs. Lesser, Schede, and Tillmanns, and the first number commenced with April 1st. It will give an epitome of surgical literature at home and abroad, and will also, like its analogues, contain short original articles.

IDENTIFICATION OF THE REMAINS OF THE LATE DR. LIVINGSTONE.—Sir William Fergusson, with several other gentlemen, made an examination, on the 14th of April, of the remains of the body brought to London from Central Africa, and purporting to be those of Dr. Livingstone. The question of identity rested upon the existence of an ununited fracture of the humerus, caused by the bite of a lion. Mr. Fergusson writes in *The Lancet* of April 18th, from which we make an extract:—

"From what I have seen I am much impressed with the ingenious manner in which those who have contrived to secure that the body should be carried through the long distance from where Livingstone died until it could reach a place where transit was comparatively easy, accomplished their task. The lower limbs were so severed from the trunk that the length of bulk of package was reduced to a little over four feet. The soft tissues seem to have been removed to a great extent from the bones, and these latter were so disposed that, by doubling and otherwise, the shortening was accomplished. The abdominal viscera were absent, and so were those of the chest, including, of course, heart and lungs. There had been made a large opening in front of the abdomen, and through that the native operators had ingeniously contrived to remove the contents of the chest as well as of the abdomen. The skin over the chest, sternum, and ribs had been left untouched.

"Before these points had been clearly ascertained, some coarse tapes had to be loosened, which set free some rough linen material—a striped, colored bit of cotton cloth, such as might have been an attractive material for the natives among whom Livingstone travelled—a coarse cotton shirt, which doubtless belonged to the traveller's scanty wardrobe, and in particular a large portion of the bark of a tree, which had formed the principal part of the package—the case thereof, no doubt. The skin of the trunk, from the pelvis to the crown of the head, had been untouched. Everywhere was that shrivelling which might have been expected after salting, baking in the sun, and eleven months of time. The features of the face could not be recognized. The hair on the scalp was plentiful and much longer than he wore it when last in England. A moustache could not be recognized, but whiskers were in abundance. The forehead was in shape such as we are familiar with from memory, and from the pictures and busts now extant. The circumference of the cranium, from the occiput to the brow, was $23\frac{1}{2}$ inches, which was recognized by some present to be in accordance with such measurements when alive.

"In particular the arms attracted attention. They lay as if placed in ordinary fashion, each down by the side. The skin and tissues under were, on each side, shrunk almost to skeleton bulk, and at a glance, to practised eyes—there were five, I may say six, professional men present—the state of the left arm was such as to convince every one present, who had examined it during life, that the limb was Livingstone's. Exactly in the region of the attachment of the deltoid to the humerus, there were the indications of an oblique fracture. On moving the arm there were the indications of an ununited fracture. A closer investigation and dissection displayed the false joint which had long ago been recognized by those who had examined the arm in former days. The Rev. Dr. Moffat, and in particular Dr. Kirk, late of Zanzibar, and Dr. Loudon, of Hamilton, in Scotland, at once recognized the condition. Having myself been consulted regarding the state of the limb, when Livingstone was last in London, I was convinced that the remains of the great traveller lay before us. Thousands of heads with a like large circumference might have been under similar scrutiny; the skeletons of hundreds of thousands might have been so; the humerus in each might have been perfect; if one or both had been broken during life, it would have united again in such a manner that a tyro could easily have detected the peculiarity. The condition of ununited fracture in this locality is exceedingly rare. I say this from my personal professional experience, and that such a specimen should have turned up in London from the centre of Africa, excepting in the body of Dr. Livingstone, where it was known by competent authorities to have existed, is beyond human credibility. It must not be supposed by those who are not professionally acquainted with this kind of lesion—which often causes so much interest to the practical surgeon—that a fracture and new joint of the kind now referred to could have been of recent date or made for a purpose. There were in reality all the indications which an experienced pathologist recognizes as infallible, such as the attenuated condition of the two great fragments (common under such circumstances), and the semblance of a new joint, but actually there was a small fragment detached from the others, which bore out Livingstone's own view, that the bones had been 'crunched into splinters.'

KINGS COUNTY MEDICAL SOCIETY.—On page 154, second column, fourth line, before the words, "The question has been asked," the name of Dr. H. Fearn should be introduced as the author of the remarks on the Veratrum Viride Treatment of Puerperal Eclampsia.

Medical Department of Life Insurance.

HYGIENE TO BE CONSIDERED BY LIFE INSURANCE MEDICAL EXAMINERS.

By A. H. SALISBURY, M.D.,

MINNEAPOLIS, MINN.

It is for the interest of all concerned that none but the best lives should be insured. It is plainly advantageous for the company, as the losses will be thereby lessened. It is equally for the interest of the policyholder, as the cost of insuring will thus be reduced and the stability of the company guaranteed. To accomplish this end medical examiners are appointed, and printed questions are furnished to guide them in their investigations. These questions are very useful to the physician, systematizing and facilitating his labor, but they do not always afford him *all* the data required for giving a correct opinion.

Unless he has made it the subject of particular study, he is too apt to base his conclusion solely upon the answers to printed questions, and give too little attention to hygienic considerations. It would doubtless be impracticable to obtain from the applicant categorical answers to such interrogatories as these:

In what kind of house does the person live?

Is it clean and well ventilated, or otherwise?

Is there any stagnant water near, and is the drainage good?

Is it shaded or open to the sun?

In what condition is the privy or water-closet, and how situated?

Is the person cleanly in his habits, or otherwise?

How often does he bathe, if ever?

Is his clothing suitable to the climate and season?

From what source is he supplied with water?

Does he take proper exercise?

What is his dietary?

Is he intelligent or stupid, educated or ignorant?

Does he employ a regular physician or a quack?

To inquire into a man's private life after this style would, no doubt, be considered impertinent; nevertheless, the information so obtained would have an important bearing upon the question which the physician is required to decide. If a person, upon examination, is found to have an unfavorable family history, both parents consumptive for instance, he is rejected, although at the time he may be the personification of robust health.

Is there not equally good reason for refusing the man who lives over a mass of decaying vegetables in his cellar, or who uses water from a well which receives the drainage from a privy or stable?

The latter is as much *predisposed* to typhoid fever as the former is to phthisis. The man who habitually exposes himself to the inclemency of the weather without proper protection, is almost as poor a risk as the one whose heart is already enlarged. The probability is, that next winter or spring he will have an attack of inflammatory rheumatism or pneumonia, and succumb either to the acute disease or some of the sequelae. The applicant for insurance who sleeps in an eight-by-ten bedroom, with his wife and three or four children, and has it hermetically sealed to keep out the cold, may have no hereditary taint, but by and by he will get a cough, neglect it, and eventually die of tuberculosis; while his intelligent neighbor, who was rejected because his mother was consumptive, understands and obeys the laws of health, breathes pure air,

never neglects a cold, and lives hale and hearty to a good old age.

The case of the intemperate eater should be as carefully considered as that of the intemperate drinker. Indeed it is questionable whether imprudence in eating does not shorten the average duration of life more than the immoderate use of stimulants. In cities, especially, it is very necessary to know the condition of the sewers and drains, and whether the streets are clean or filthy. So much has life been lengthened in modern times, by reform in this respect, that no other proof is needed of its importance. Even the direction of the street has its influence on longevity. Every physician can testify that the streets so situated that the sun, the best antiseptic we have, cannot shine into the houses, are the streets where he is most frequently called. Of course every one who violates the laws of health should not be refused assurance; but, on the other hand, if more heed were given to hygiene in issuing policies, many unprofitable risks would not be taken, while others might be accepted, which, though not the best, are rendered equal to the average by the intelligent life of the applicant.

HEALTH OF OPERATIVES WHO ARE EXPOSED TO CERTAIN KINDS OF DUST.

By DR. GOTTLIEB MERKEL.

(Translated from the German.)

THE kinds of dust referred to below have never been demonstrated to be present in the tissue of the lungs, but the prevalence of certain affections of the lungs* among those habitually exposed to this dust justifies us in considering it as in a great measure the cause of these affections.

First among these varieties should be mentioned *wood dust*. The molecules of this dust are of varying hardness and form, and under certain circumstances are present in enormous quantities in the air.

The classes of persons most exposed to this dust are the joiners, whose average duration of life, according to all authors, is not quite 50 years; the toy-makers; the carpenters; the wheelwrights; the turners in wood, and those employed in saw-mills. Among the latter, special mention should be made of those who work in lead-pencil manufactories, particularly those who are employed in the rooms where the cedar boards are sawed, and where the grooves for the lead are planed out in the handles. The dust is very abundant and dense in these places, and, according to our observations, consumption is a frequent disease among the workmen. We are not able, however, to furnish statistics on this point.

The following table, which has been prepared by Dr. Ludwig Hirt, gives the relative frequency of pulmonary affections among workers in wood.

Out of 100 sick workmen there were:

	With Consumption.	With Chronic Bronchitis.	With Emphysema.	With Pneumonia.	Average Duration of Life.	Mortality per cent.
Joiners.....	14.6	10.1	3.9	6.0	49.8	1.89
Carpenters.....	14.4	6.5	6.9	6.9	53.7	—
Wheelwrights and Carriage-makers	12.5	9.2	1.3	5.2	—	—

*The varieties of dust which have been discovered in the lung tissue receive their full share of attention in a previous portion of the essay from which the above extract has been made.—EDITOR.

To the same category belong the workmen employed in the chicory, madder, dye-wood, and Peruvian bark stamping-mills. But the number of these is so small that it is impossible to draw any accurate conclusions.

The second variety under consideration is the dust of the different kinds of grain and flour.

It is, of course, a well-known fact that the dust which is produced during the operations of threshing, cleaning, and measuring the various kinds of grain (rye, wheat, barley, and oats), and which consists of fragments of the stalks, leaves, and chaff, together with a certain amount of earth accidentally present, produces a very irritating and injurious effect upon the organs of respiration. But the harm which it might produce is almost entirely obviated by the shortness of the time during which the workmen are exposed to the injurious influence of the dust.

On the other hand, the millers are exposed almost continuously to the irritating influences of the dust, and as a consequence they furnish a large contingent to the number of sufferers from pulmonary diseases. The inhalation of the grain and flour dust is not the only injurious element to which they are exposed: a large portion of the miller boys are kept employed for a certain length of time polishing the stones.

According to Hirt, out of 100 sick millers there will be found 42 suffering from acute or chronic affections of the lungs, namely, 10.9% with consumption; 9.3% with bronchitis; 1.5% with emphysema, and 20.3% with pneumonia. The mortality of millers is stated by the same authority as 1.7 per cent., and the average duration of life as 45.1 years.

The bakers and confectioners are somewhat more favorably situated in this respect, as they are exposed only to the flour dust.

The dust of wool constitutes the third variety. The fibres of wool, which under the microscope present a strong resemblance to hairs, and enter the lungs with the inbreathed air, do not seem to exert a specially injurious influence upon the health of the wool-workers. While it is true that this class of operatives does not as a rule enjoy good health—and this is especially so of the girls employed in spinning-mills—still this is in great measure to be accounted for by other injurious influences, such as the overheated condition of the spinning-rooms, in which the air is at the same time damp and filled with the fumes of oil.

The cloth-sheerers are exposed to an atmosphere much more heavily laden with wool fibres. According to Hirt's observations, made in Spremberg in 1869, there were 100 sick out of a thousand cloth-shearers. Twenty-five per cent. of these were affected with diseases of the respiratory organs, namely, 7-10% with consumption, 6-8% with bronchitis, and 2-4% with emphysema. The mortality was from 1 to 1.5 per cent., and the average duration of life 57.5-59 years.

According to the reports of Sommerbrod, the women operatives upon sewing-machines suffer appreciably from the influence of wool-dust. In the shoddy manufactories, where solid masses of wool are again reduced to shreds before the material is manufactured into cloth, the operatives are also exposed to the same influences. Although the English accounts picture this occupation as one of special danger to the lungs of the operatives, nevertheless, corroborative statistics are wanting, and the experience thus far of German shoddy manufacturers does not show the occupation to be one of such decided injuriousness to health. In the manufacture of silk goods, whose fibres are extremely thin, smooth, and flexible, dust is sometimes produced, as, for instance, in the carding process. The poor health, however, which some authors mention as universal

among the silkworkers, may rightly be attributed to other causes, as, for instance, their improper and dissolute mode of life—so well known as to be even a by-word. Accurate statistics on the subject are wanting.

Hair dust, which constitutes the fourth variety under consideration, consists not only of the fragments of the hairs, but also of the particles of dirt which cling to them. In the case of the hat-makers still another element has to be taken into consideration: in dressing the fur they make use of a poisonous solution, the nitrate of mercury, to destroy the roots of the hairs. Hirt reports the cases of three old horse-hair pickers, in whose lungs after death he found the lesions usually designated as *Chalicosis pulmonum* [deposit of stony particles in the lungs]. This would seem to indicate that only the particles of dirt which cling to the hairs remain behind in the lungs after the inhalation of the dust. A genuine hair or bristle dust is only to be found in the workshops of the brushmakers.

As the furriers do not beat the furs continuously, the injurious effects produced are slight and transient in character. Those hatmakers, however, whose duty it is to shear the hares' hairs, do not escape so lightly. Besides the dust generated by cutting off the projecting hairs, there is also that produced by shaking off the dried particles of nitrate of mercury, the inhalation of which calls into existence a peculiar train of symptoms, which is known under the term of "hare-clippers' disease." The description of this, however, will be given in another place. Very much the same kind of dust is generated by the process of manufacturing felt.

We possess no special knowledge concerning the feather-dressers, but it would seem, from Hirt's reports, that they too do not enjoy good health, but suffer a good deal from pulmonary affections.

We copy from Hirt's work the following facts relating to the diseases of the brushmakers and workers in hair goods:

Out of 100 sick individuals there were

	With Con- sumption.	With Chronic Bronchitis	With Em- physema.	With Pneum- onia.	With acute Catarrh.	Average Duration of Life.	Mortality per cent.
Brushmakers.	49.1	28.0	—	7.0	12.2	—	1.6
Hair-dressers.	32.1	17.8	3.4	10.7	21.4	57.9	—
Saddlers.....	12.8	7.5	2.5	5.0	41.1	53.5	2.39
Upholsterers.	25.9	11.7	2.5	10.3	24.9	—	—
Furriers.....	23.2	10.7	2.7	8.1	23.3	59.5	—
Hatmakers....	13.3	6.7	4.7	5.6	33.3	51.6	2.9

The dust of horn and bone constitutes the fifth variety. The ultimate particles composing this dust vary very greatly in shape and size. According to Hirt's reports, consumption is a comparatively frequent disease among the workmen in the bone manufactories. Where sawing has to be done, there is produced a very fine and dense dust; but where the bone is turned, the fragments are so large as to fall at once to the ground, and so they do little or no harm.

In this connection we might mention a case which occurred within our own observation:—

A turner in horn, 27 years of age, died of typhus fever in the City Hospital. At the post-mortem examination, the apices of all five lobes of the lungs were found to be the seat of a very marked rarefaction of the lung-tissue, and to contain unmistakable particles of horn-dust. Of course it is impossible to say whether the rarefaction of the tissue was the cause or the result of the deposit of dust. We should bear in mind, however, that all turners injure their chests more or less by the way in which they use their tools.

THE DUTIES OF THE MEDICAL OFFICER.*

By EDWARD H. SIEVEKING, M.D.,

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS; PHYSICIAN TO ST. MARY'S AND THE LOCK HOSPITALS; PHYSICIAN EXTRAORDINARY TO THE QUEEN, ETC.

The regular employment of medical men to examine candidates for life insurance is a practice of comparatively recent date. The custom of the old offices, prior to about 1820, was for each life proposing to sign a very distinct and binding declaration, to the effect that the individual had not had "cow or small-pox, or any other disease tending to shorten life." No mention seems to have been made of family history. The proposer had to give a reference to "two persons of good repute, one, if possible, of the medical profession." Parties who did not appear before the directors, or who could not refer to a medical gentleman, were required to give a reference to three persons.†

Since that time the entire aspect of life insurance business has undergone a change; and while the companies have learned to appreciate the value of skilled medical advice, the members of the medical profession have acquired a direct pecuniary interest in promoting to their utmost the great social and economic principles which underlie insurance transactions. We have tried in vain to ascertain approximately the amount of honoraria paid in this way to the medical profession; but a little reflection will teach the reader that it must be very considerable, seeing that there is scarcely a medical man in the kingdom who is not more or less often applied to for his opinion as to the value of lives for insurance.

The duties which the medical officer of an insurance company undertakes to perform are of a very responsible character, as they involve both the happiness of the applicant and the welfare of the company. The rejection of a candidate not only interferes with his plans of making provision for his family, but implies the existence of a morbid taint or of actual disease, calculated to abridge his life, which he may not have suspected, and the revelation of which is likely to create serious alarm. If the examination is carefully conducted, and facts bearing upon the prospects of the life of the individual are overlooked or falsely estimated, the office will be mulcted by having to pay a claim before it ought to become due. A refusal to pay may be justified under circumstances of serious concealment, of actual fraud or conspiracy; but juries naturally tend to the side of the claimant's representatives, unless the evidence is of a very glaring character; and owing to the odium entailed, and to the consequent loss of business, companies shrink from appearing in court, unless they can bring overwhelming proof that they are victims of deception, against which they had taken every reasonable precaution. The history of life assurance reveals many instances of gross frauds perpetrated upon life insurance companies; personation, forgery, and murder have been employed, and frequently with success;‡ these are not generally matters for the professional consideration of the medical adviser, who has to guard chiefly against attempts at concealing facts that indicate depraved habits and a tainted constitution. In examining the statements made by the applicant and by his friends, he has to exercise discrimination and judgment, so as to note

any discrepancies and to seize every indication of impaired vitality, which a single personal examination often fails to show. A case recently came under our notice in which an office successfully resisted the payment of a large claim on the ground of the concealment of facts, which certainly would have prevented the acceptance of the life had they been known when the policy was taken out. A gentleman died, within a short time of effecting an insurance, at a distant continental watering-place. An accident suggested to the watchful and intelligent actuary that fraudulent representations had been made as to the deceased's previous health and habits. By following up the clue, and calling in the assistance of the detective department of the police, the deceased policy-holder was shown to have been a victim of intemperance, through which he had, not long before effecting the insurance, become the inmate of the police cell, if not the lunatic asylum; and the collected evidence proved so conclusive, that instead of the company being called upon to pay a claim of £2,000, it was mulcted only in the expenses of its inquiry. Tardieu* gives a curious illustration of the ingenuity brought to bear upon this species of fraud. A bankrupt, having assured his life in Paris, in December, 1864, for 100,000 francs, was reported soon after to have died in London, of heart disease. But it turned out that the policy-holder had registered his own death in London, attended his own obsequies, and obtained a ship and cargo on the strength of the expected insurance. Murder and suicide have also, even in modern times, played a part in insurance business. Thus, for instance, we find in the same author a case of a Swede, Hoffstedt, who was insured by a man of the name of Swinson, with the Caisse Paternelle, in France, with the understanding that Swinson was to provide the former with brandy for the purpose of drinking himself to death. The brandy was not expeditious enough, so arsenic was administered. Fortunately this was discovered, and the policy cancelled.

We shall see that the question of temperance is one of great, and, unfortunately, very frequent difficulty. People entertain very different views as to where intemperance begins, and, excepting where its effects have already left a permanent impress on the system, the indications are by no means such as to enable the medical examiner to trace its existence with certainty.

Although the necessity of a medical scrutiny into the value of all lives submitted for insurance is now an acknowledged fact, the manner in which the inquiry is conducted varies in different offices. The physician had little or nothing to do in the early days of insurance, which was then regarded in the light of any other contract between two individuals not necessitating the interference of skilled evidence. But as time wore on and the conditions of the contract became better understood, it was found that neither party was in a position to value the data upon which it was to be based, unless the state of health of the applicant and the various contingencies bearing upon his prospect of life were duly estimated. The physician now became an essential aid in the furtherance of life insurance business. It soon became apparent that although he might be fully competent to arrive at a satisfactory result by any method of examination that was most convenient to himself, it was necessary for future reference, as well as to enable the Board to form an opinion upon the various points at issue, that his reports should be made in a definite and uniform manner. Hence all offices now require the

* An extract from Dr. Sieveking's recent work, "The Medical Adviser in Life Assurance."

† See History and Constitution of the Equitable Society, by William Morgan, F.R.S.

‡ Ample illustrations are given in Mr. Francis's Annals, Anecdotes, and Legends of Life Assurance: London, 1853.

* Etude Médico-légale sur les Assurances sur la Vie. Paris, 1866, p. 113.

examination to be conducted according to a certain rule; and a fixed series of questions are issued, so that a record may be at hand which establishes both the bona fides of the policy-holder and the manner in which the inquiry into his health was made.

The great difficulty in framing the queries has consisted in steering the middle course between pedantic minuteness on the one hand and too great breadth on the other. The former may prove vexatious to the applicant and irritating to the physician; but the latter may err by not suggesting subjects that a careless or much-occupied practitioner may slur over or forget. The medical man should remember that negative evidence is often as important as positive indications, and that while he has the opportunity of a personal interview with the applicant, the Board, who have to decide the ratable value of the life, do not possess this advantage. It often happens that the young practitioner, or one who knows little of the difficulties of framing a correct estimate of probabilities, resents the inquiries made by an office as an impertinence and as an imputation upon his mode of reporting; but any one who will bear in mind that, important as his functions may be, the decision must ultimately rest with the Board of Directors, and that they are responsible for the general business of the office, will also admit that they have a right to ask for such information as they may deem necessary to guide them. Many careless and slovenly reports have come to our notice, and this is the less to be justified now that the medical profession benefit pecuniarily to a very large extent by the system at present in force. It may be laid down as a general rule that the best men give the most satisfactory and detailed reports, as they fully appreciate the aid they afford towards the development of a social scheme of the highest value and importance.

The proposal for assurance, or the chief facts it contains, are submitted to the medical officer, and the statements subscribed to, on it, afford useful data for comparison with the facts elicited by the examination; nor should the replies given by the proposer's friends be overlooked for the same reason. The manner in which they respond to the inquiry about the temperance of the applicant, frequently affords a clue to further investigation, which he himself might withhold.

The age is an important element, not only as regards the amount of premium to be paid, but also in reference to the *vis vitalis* of the individual. It is proper that he should appear the age he assigns; but while it cannot be regarded as otherwise than generally favorable if he should look younger, it is decidedly the reverse if he looks much past his registered age, as this indicates precocious development in the young; and in those who have attained full manhood it is a sign of premature decay, depending, possibly, upon the anxiety and depression of business, upon exhausting diseases or excesses, or simply upon want of the normal vigor. In any of these cases the prospect of longevity would be reduced.

As the rates of insurance are based upon the calculated prospect of life at each age, the medical man need be under no apprehension in recommending persons of advanced age, who are in good average health, to insure. Our own experience accords with the conclusions arrived at by Mr. Neison, that the generally received opinion as to the insecurity of old lives* is fallacious, and that they are paying risks. They have passed through the dangers that beset early life, have learned how to take care of their health, and have

probably attained that competency and contentment which are among the best guarantees for a prolonged existence.

The effects of intemperance, as proved by Mr. Neison, exhibit themselves chiefly at a comparatively early age, the maximum rate of mortality in intemperate lives occurring between 41 and 50, so that a person who at that age gives evidence of habitual temperance has escaped one of the most prevalent causes of degeneration of the tissues, and may boast of his age being

* As the last winter,
Frosty but kindly."

The question of temperance is unfortunately one to which the special attention of medical officers has to be directed, both in the case of male and female candidates for insurance. The difficulty that we have to deal with consists in the very great latitude in the definition of intemperance. But for the purpose of life insurance the broad line may be laid down, that the habitual spirit-drinker, and especially one who is found to take strong drinks early in the day, ought to be declined altogether. The beer and wine drinker does not shorten his life frequently by excess, but there is scarcely a degenerative condition of the body that may not result from the abuse, or rather the habitual use, of ardent spirits.

It is doubtful whether teetotallers can be regarded as very good lives, because they are frequently reformed drunkards; but when they have been advocates of the system before they had committed any excesses, or when they have taken the pledge before degenerative changes had occurred in the body, one cannot doubt that the teetotaller may be regarded as a good life. "The reformed drunkard," as Dr. Brinton justly observes, "is not a good life; his repentance, as regards his physical constitution, often comes too late. Many months or even years of the most complete abstinence scarcely suffice to restore his probabilities of existence to a level with those of the temperate user of alcohol. Setting aside the not inconsiderable chances of his relapsing into old habits, his constitution often seems to have a peculiarly treacherous character; its apparently robust health consuming away with unusual rapidity under a moderately severe attack of any acute disease."

Excess in drinking is admitted by all physicians to be the frequent direct and indirect cause of fatal illnesses. Gluttony is less to be regarded as a cause of mischief, because the system more readily adapts itself to a certain excess of alimentary supplies; and solid food not being so easily taken up and assimilated, a check takes place spontaneously to the introduction of more than a given quantity of solid food. The truly temperate man takes as much food and beverage as he requires for the due performance of all his functions, and not more of one or the other; and the common experience of man, which is supported by scientific observation, is to the effect that our ordinary food goes farther and lasts longer, if with it we consume a quantity of beer or wine, enough perhaps to exhilarate, but not sufficient to confuse or weaken the intellectual powers.

A MAN was recently examined in this city who could expand his chest from 32 to 40 inches. As several members of his family had died of consumption, he had for some years past cultivated the habit of expanding his chest to the utmost, in the hope of thereby diminishing his liability to have the same disease.

* On the Medical Estimate of Life for Life Assurance, by Stephen Ward, M.D. London, 1857.

A MORTALITY EXPERIENCE OF TWENTY-FIVE YEARS.

WE are indebted to one of our New York life insurance companies for the following brief statistics:

During a period of twenty-five years the number of deaths which occurred among the policy-holders of the company amounted to 2,202. The causes of death, arranged in groups, are the following:

CLASS OF DISEASE.	NO. OF CASES.
Zymotic.....	401
Nervous.....	339
Respiratory.....	613
Circulatory.....	135
Digestive.....	307
Genito-urinary.....	80
Uncertain seat.....	118
Integumentary.....	32
External causes.....	175
Age.....	2

In the January 15th number of *THE RECORD*, the causes of 1,000 deaths were given from the records of another company. Comparing the percentages of the deaths in the two companies according to the groups of diseases, we obtain the following:

	1,000 deaths.	2,202 deaths.
Zymotic.....	19 per cent.	18 per cent.
Nervous.....	15 "	15 "
Respiratory.....	36 "	28 "
Circulatory.....	6 "	6 "
Digestive.....	8 "	14 "
Genito-urinary.....	3 "	4 "
Uncertain seat.....	4 "	5 "
Integumentary.....	— "	1 "
External causes.....	7 "	8 "
Age.....	— "	— "

It is interesting to notice the close correspondence between the two lists, except in two of the classes, namely, the respiratory and the digestive. It is in these very classes, however, especially in the respiratory, that we should most expect to find variations in the experiences of different companies.

Correspondence.

LET THE GOOD WORK GO ON.

TO THE EDITOR OF THE MEDICAL RECORD.

WHILE I am indebted to a life insurance company for the privilege of reading *THE RECORD* regularly, I cannot at the same time resist the inclination to say a few words about the strange ways of agents and the still stranger ways of certain companies. The evils of which I complain are not by any means peculiar to my own experience, but are undoubtedly encountered by scores of medical examiners in every part of the country, for the life insurance solicitor is the same everywhere.

Before mentioning these, let me remark that the things most needed in both agent and examiner are, honor and integrity. The physician, furthermore, should be well posted in auscultation and percussion, and should have excellent diagnostic skill in diseases of the chest. He should also be familiar with the chemical tests necessary to ascertain the condition of the urine. But, above all things, he should deal honestly with the company. If he en-

tertains doubts in any case, he should let the company have the benefit of them. Two years since I rejected an applicant on account of mitral regurgitation of the heart. The agent remarked at the time that "I had lost him two hundred dollars." I replied that it was better for the company to pay him two hundred dollars, if need be, rather than to lose ten thousand by issuing the policy. Six months afterwards the man was dead. A few years since an agent of the — Life Insurance Company called on me, and, stating that he was the accredited agent for said company, expressed the wish that we would get along well together. I remarked that it would not be my fault if we did not. A few days later I received a letter from Dr. —, medical officer of the home office in New York, enclosing a copy of this agent's letter to him, in which it was stated that he found a large number of persons in Springfield ready to be insured, but they were unwilling to come to me for examination, as they were my enemies. The letter ended with the request that Dr. — might be appointed examiner in my place. Now, had it not been for the promptness of the home medical officer in asking me the facts in the case, the company would have probably suffered, for the doctor whose name the agent suggested was a homeopath of the lowest order, and this agent employed him in his family, and undoubtedly intended to "use" him. This man was, of course, dismissed from the employ of the company, but he very soon became the agent of another prominent company, whose name I shall in all charity conceal. This company also instructed him to employ me as medical examiner. Before long he brought an applicant to me for examination. On looking over the application I noticed that the man's occupation was put down as that of a farmer. As I knew that the fellow was a saloon-keeper and gambler, and patronized his own bar to excess, I feigned that I could not understand why he had been marked as a farmer. The agent replied, in a low tone, and with a knowing look, wink, and nod of the head, "That's all right." Not wishing to have a fuss with the fellow, I recommended him, but wrote at once to the medical officer at the home office, stating all the facts. The result was, the man was rejected. In a few days the agent came with a letter from the general agent, stating that the Medical Officer of the Home Office had rejected the application, and requesting me to write to the company, urging them to issue the policy. This I refused. Subsequently he brought me a second letter from the General Agent, which read as follows:—"Cox must have written privately, as the home medical officer says this man drinks whiskey. — Cox! Don't bring him another risk for examination." Nor did he bring me another risk, nor was this agent removed, nor did the company investigate the matter. I thought this was a poor reward for my fidelity to the company. But where has that company gone? "*To where the woodbine twineeth*"—where all companies should go which do not respect competent and faithful medical examiners.

I cannot agree with your San Francisco correspondent, who says that it were better to do away with medical examinations, for I believe that medical examiners are the main guardians of life insurance companies. At the same time, it is amazing how slow the companies are to appreciate the truth of this. They are exceedingly anxious to get agents, but very few of them trouble themselves about their medical examiners, or show any anxiety to secure good men, and keep them after they have secured them.

GEORGE M. COX, M.D.

SPRINGFIELD, MO., April 9, 1874.

VERY OLD MEN.*

A PENNSYLVANIA gentleman called yesterday to say that Simon G. Troop, the Legislative Rip Van Winkle referred to in Friday's *Tribune*, was appointed one of the judges of Monroe County, Penn., by Gov. Geary, after he had passed his 80th birthday, and he was now discharging the duties with marked ability. He added that the climate of that portion of Pennsylvania contributed to the longevity of its citizens. George Labar, a resident of Monroe County, is 112 years old. Mr. George Trivle, of Daleville, is the oldest landlord in the State of Pennsylvania, having kept tavern ever since licenses were granted by the Governor of the State, and is now, at the age of 109 years, proprietor of the hotel at Daleville. The ages of these two veterans, as Mr. Gilmore assures us, are both well authenticated.

And yet there is an opinionated Englishman, whose name I do not remember, making all sorts of efforts to discredit Capt. Lahrbush, who completes his 108th year to-day. Fortunately, the existence of unquestionable evidence of the fact that Capt. Lahrbush was an officer in the British army before the commencement of the present century, destroys the base upon which the Captain's assiduous endeavors to erect a superstructure. Corroborative evidence of the accuracy of Capt. L.'s memory, the truthfulness of his statements and the integrity of his character, is found in his daily conversation. Those who know him best, and see him most frequently, entertain no doubts concerning his age. The accuracy of his memory in relation to events which occurred ten years before and fifteen years after the beginning of the present century, is perhaps the most remarkable trait in the character of this very remarkable man. In illustration, take the following incident: Captain Lahrbush accompanied me one day last winter to the residence of my cherished friend, the late Hugh Maxwell. In the course of a long conversation about the wars in which Capt. Lahrbush had served, the latter was describing a campaign in India toward the close of the last century. Mr. Maxwell inquired if, at that time, he became acquainted with an officer bearing his name. Capt. L. replied that he remembered Lieut.-Col. Maxwell in India, but that he did not make his acquaintance until several years afterward, when stationed at the Cape of Good Hope, where Col. Maxwell came to enjoy his "leave." Mr. Maxwell asked why the officer used up his "leave" at the Cape, instead of going home. Capt. Lahrbush replied that officers serving in India could go no further west than the Cape of Good Hope without loss of pay. Mr. Maxwell then requested his granddaughter to bring a letter from his library; that letter being from Mr. Maxwell's uncle, written at the Cape of Good Hope, and bearing the date indicated, exactly verified Capt. Lahrbush's statements. Lieut.-Col. Maxwell had, for economical reasons, passed his leave of absence from the army at the Cape, which place, on account of its salubrious climate, was a favorite resort for British officers. Capt. Lahrbush recently received a message, by a New York lady who had been residing some time in Paris, from the Count de Waldeck, who remembers him, while both were at Madras, in 1798. The Count, although two years older than Capt. Lahrbush, enjoys good physical and mental health.

Capt. Lahrbush enters upon his 109th year in good health and spirits. He is a member of the Rev. John Cotton Smith's church, where, on the corner of Fifth ave. and Tenth st., he is a regular attendant. He

dined with us to-day, as is his frequent habit on Sunday, and if those who cavil about his age could have listened to his conversation for an hour or two, they would have had their doubts removed. His familiar description of most of the cities of Europe, India, Australia, Jamaica, etc., etc., prove him to have been not only a great but a most observing and intelligent traveller. He speaks the French, German, Dutch, Spanish, and Portuguese languages.

It was quite a luxury, he said, to meet, as he did the other day, a Hollander as a conductor on a Third ave. car, with whom he had a pleasant conversation in that language.

NEW YORK, March 8, 1874.

MEDICAL EXAMINERS' BLANKS.

THIS being a time when many of the companies are considering the question of introducing new forms of blanks for their medical examiners, we beg leave to submit the following translation of a form used by one of the prominent life insurance companies of North Germany.

The blank in question bears at its head the title of "Health Certificate," and commences with an appeal to the examiner to be very precise in all his answers to the printed questions, which are all addressed directly to him. He is also reminded of the fact, that upon his skill, carefulness, and truthfulness depend the interests of many families. With this in mind he is to furnish to the company the most complete picture possible of the person upon whose life it is proposed to issue a policy. Then follow these questions:—

1. How long have you been acquainted with the above-named person?
2. How long have you been his attending physician?
3. When did you see him last and satisfy yourself of his condition of health?
4. What is his general build, as regards Height, Weight, Corpulence or leanness?
5. What is the hue of his complexion and the expression of his countenance?
6. How is the chest shaped, and what are the proportions and form of the neck?
7. What is the condition of the abdomen? Is the liver or the spleen enlarged? Is there any hernial swelling?
8. Are the limbs, as well as other parts of the body, free from any defect, fracture, curvature, exostosis, enlarged veins, etc.?
9. Do the different organs of sense perform their functions normally? If not, state in what respect they are deficient.
10. What are the results of a physical examination of the chest and abdomen by percussion and auscultation?
11. Is the respiration full, easy, and deep, and free

* A copy of a recent letter from Thurlow Weed to the Editor of the *Tribune*.

from abnormal sounds? Does the chest expand uniformly in all directions? Are the respiratory movements performed without any noticeable effort; and can they be kept up for a reasonable length of time without exciting cough?

12. What is the condition of the voice? Is it clear, resonant, and free from hoarseness?

13. What is the condition of the circulation, as judged by the pulse-beat at the wrist and the action of the heart in the precordial region? Is there any noticeable pulsation in the abdominal region?

14. What is the condition of digestion and the other functions of the body?

15. What diseases, ailments, mental disturbances, bodily injuries or fractures has the above-named person had or been treated for by another physician before you became his medical attendant?

16. What diseases, ailments, mental disturbances, bodily injuries or fractures has he consulted you for, and at what time was the treatment in each case carried out?

17. How did he recover from these ailments or injuries, and what effects have they left upon his health?

18. Does the person above named now require, or has he ever required, for prophylactic or curative purposes, any form of bleeding or a course at the "baths," "springs," "vegetable diet" or "whey-cure establishments?" If so, state the particular reasons.

19. Is there any hereditary disease in this person's family, or any disease that has frequently made its appearance among its members; and does he show any signs of being predisposed thereto?

20. Has he had the small-pox or the cow-pox, and did the latter run its regular course (to be judged, of course, by the condition of the scar of inoculation)?

21. Is the person above named at the present time in good health and free from all disease?

22. Do you also consider him free from the *seeds* of any disease of a dangerous nature?

23. What influence do his surroundings, occupation, and mode of life have upon his health? Is he moderate in his use of spirituous drinks?

24. In the foregoing answers have you omitted anything pertaining to the person's vital functions, external appearance, mode of conducting himself, physical strength, temperament, etc., which might be of value in determining the nature of the risk?

25. Are you related to the above-named person, and in what degree? *

I declare that I have written the above conscientiously and with a full knowledge of my official duty, and have concealed nothing pertaining to the present or past condition of health of the person therein referred to.

* In the additional instructions it is stated that in case the attending physician is a near relative of the person examined, his certificate must be testified to by another physician.—EDITOR.

The casual reader might think that the certificate given above differed but little from those in use by the great majority of American life insurance companies; but on closer examination he would find several very important differences between the two. In the first place, the person's usual medical attendant becomes *ipso facto* the company's medical examiner. We believe this custom does not prevail with a single American company. In the second place, a complete and conscientious answering of the German questions necessarily implies a degree of thoroughness in the examination which the American method of insuring lives does not admit of carrying out. The German plan puts the person to be examined on very much the same footing as the recruit, while the American expects the medical examiner to make a good guess at the person's physical condition and chances for longevity. On the other hand, certain things are practicable in an old and well-settled country like Germany, which could not possibly be carried out in a growing country like ours. Still the American plan might, we think, be improved by adopting some features of the German.

Miscellaneous.

WHAT IS HABITUAL INEBRIETY?—Judge Shipman, of the New York U. S. Circuit Court, in a recent charge, said: "I do not suppose if a uniformly temperate man should be overcome by liquor, and die in consequence of a single debauch, that he could be said to have died in consequence of the *habitual* use of intoxicating liquor. It is not for me to say how long the use of liquor must be continued to make it habitual. The law prescribes no particular length of time that I am aware of. You are to judge of this as of any other fact of the case. The testimony on the part of the defendants is that his death was caused by the excessive use of alcoholic liquors and of opiates, and this statement is contained in the physician's certificate of death, and is exactly or substantially contained in the verdict of the coroner's jury. If he used liquors habitually and excessively, and also used opiates for the purpose of allaying the excitement of liquor, and they combined to cause and did cause his death, and the liquor directly, materially, and effectually contributed to his death, then the policy was voided. If he used an undue quantity of liquor habitually, and in the wild and excited state which liquor creates, resorted to overdoses of opiates to produce quiet, and so from the combined effects of these stimulants and narcotics died, and the stimulants directly, materially, and effectually contributed to his death, then the policy is not binding upon the company."

MEDICAL EXAMINATIONS.—From the *Insurance Times* we learn that the Bremen Medical Society, after mature deliberation, has recently adopted the following resolutions:

Resolved, That when a company requires a medical examination by its regular medical examiner, it shall be conducted at the premises of the physician. A family physician shall give his certificate only at the personal request of his patient, or, if at the instance of the company, only with the patient's express consent. Certificates shall be delivered by physicians sealed, and the sealed certificates shall be opened only by the officers of the company, never by the agent. The grounds assigned by a physician for refusing an application shall be in no case divulged to the public,

and the members of the society bind themselves not to make examinations for any company which shall disregard this provision.

Fees shall be charged for appearing and testifying as a witness, for records of diseases, *post-mortem* examinations, and for all reports other than upon the ordinary examination, in addition to the regular examination fees.

TAMPERING WITH MEDICAL CERTIFICATES.—The following case, which occurred recently in the State of Connecticut, illustrates one of the ways in which a bad risk can be foisted upon a company.

Not many months since an applicant was brought before one of the regularly appointed medical examiners of a prominent life insurance company for examination. His health was poor, and the examiner unhesitatingly rejected him. A short time afterwards the physician was astonished to hear "that Mr. X., whom he had recommended for a policy a few months previously, was dead." As the examiner was known to be a very careful man the company sent a special agent to investigate the case, and thus it was discovered that the physician's unfavorable report had been changed, by means of erasures and the introduction of additional words, to one of favorable purport.

THE HEREDITARY CHARACTER OF CANCER.—In medical circles there has always been a great deal of discussion upon the question, whether or not cancer be hereditary. The following recently discovered letter from Dr. Short, who was the chief medical officer at St. Helena at the time of Napoleon's death, will perhaps be of interest in this connection. It reads as follows:—

"St. Helena, May 7th, 1821.—You will doubtless be very much astonished to learn that Napoleon died on the 5th of May, after a prolonged illness. His disease was cancer of the stomach, which undoubtedly began to develop already many years ago, though it was only during the past few months that it took on a condition of ulceration. A few days before his death I was frequently called to take part in the consultations which were held, but never saw him professionally—owing to his unwillingness to see strangers—until just before his death. The face of the dying man was the most beautiful I ever saw; his features were characterized by the most perfect peacefulness and gentleness. The following day I was present at the *post-mortem* examination, which was made at Napoleon's own special request, for the purpose, as he said, that his son might be put upon his guard, in case the disease proved to be hereditary in its nature. During his entire illness he had not shown the slightest disposition to complain, but maintained to the very end his wonderful mastery over himself. It appears that Napoleon's father died of the same disease, and his sister, the Princess Borghese, was also supposed to have died of it. Hence climate and mode of life could have had nothing to do with causing his death."—*Deutsche Versicherungs-Zeitung*.

STATISTICS OF SUICIDES IN VIENNA FOR 1873.—There were 216 suicides (172 in 1872) within the police districts of Vienna during the year 1873. The largest number occurred during the months of May and December. 182 were males, 34 females. The youngest was 13 years old, the oldest 80. 77 hanged themselves, 52 shot themselves, 33 took poison, 30 were drowned, 10 severed blood-vessels or cut their wind-pipes, 10 threw themselves down from great heights, 2 stabbed themselves, and the same number allowed themselves

to be run over. Twelve cases occurred in January (11 males, 1 female); eight in February (all men); sixteen in March (14 men and two women); twenty-one in April (12 males, 9 females); twenty-four in May (19 men, 5 women); 19 in June (16 men, 3 women); 19 in July (17 men, 2 women); 17 in August (15 men, 2 women); 15 in September (all men); 21 in October (18 men, 3 women); 18 in November (15 men, 3 women); 26 in December (22 men, 4 women). Loss of fortune, anxiety in regard to obtaining food, incurable diseases, and, finally, disappointed love, were generally the causes for the deed.—*Deutsche Versicherungs-Zeitung*.

THE EMPRESS EUGÉNIE INSURED FOR \$200,000.—As the report had gone abroad that the young Prince Napoleon was insured for a large amount, which would be paid to him on becoming of age, the *Monteur des Assurances* denies in toto the truth of the report and gives what it declares is the true version. It reads as follows:—The Empress Eugénie, a short time after the birth of her son, founded "The Imperial Orphan Asylum," and at the same time insured her life for 2,000,000 francs, with the intention of leaving this sum in her will to the institution she had founded. Since that time, however, the amount of the policy has, by mutual agreement, been reduced to half the original sum. This transaction gave rise to the circulation of the most fabulous stories among the people; and, in the days of the Commune, the insurance companies had very great difficulty in dissuading the leaders from exacting a heavy tax on what they declared was "money which belonged to France."

The amount is distributed among nine different French companies; and the Empress, besides having to pay the extra 11 per cent. for crowned heads, not only pays the premiums without any reduction, but even refuses to enjoy the dividends.—*Ibidem*.

EFFECTS OF INTEMPERANCE ON LONGEVITY.—Mr. Neison, in a very elaborate paper on the rate of mortality among persons of intemperate habits, shows that the expectation of life of intemperate persons is much below the average; and that an intemperate person of 20 has reduced the average expectation from 44.2 years to 15.6; a person of 30, from 36.5 to 13.8 years; a person at the age of 40, from 28.8 to 11.6 years; and also that while diseases of the nervous system and digestive organs give rise to 15.9 per cent of deaths in the population at large, they form 50.40 per cent of all deaths among the intemperate.

Intemperance reduces the expectation of life more in the upper classes than among mechanics and tradesmen.

Mr. Neison finds that from the age of 16 upwards the relative mortality of intemperate persons exceeds that of the general population of England 3.25 times. At the term of life 21 to 30 the mortality is upwards of five times that of the general community, and in the succeeding 20 years of life it is above four times greater. He offers the consolatory remark that the drinking practices of society have improved during the last quarter of a century, and that what (in 1851) was commonly regarded as free living, would some years since only have been regarded as moderation. "In like manner," he adds, "it may be hoped that the usages of society will continue to improve; and, at no distant date, the habits now considered not to exceed the bonds of moderation be altogether unknown in polite and refined society."—*The Medical Adviser in Life Assurance*.

Original Lectures.

LECTURE UPON THE GENERAL THERAPEUTICS OF THE NERVOUS SYSTEM.*

By E. C. SEGUIN, M.D.

PART I.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—I have thought that the last hour of your survey of nervous diseases could not be better spent than in a rapid review of certain principles of therapeutics, and in a partial study of the remedial agents classified as much as possible in accordance with these principles. In offering you the following classification, I wish to warn you that it has little in common with the therapeutic propositions which you will find in text-books, whether upon the practice of medicine or upon diseases of the nervous system. Inasmuch as the ground to be gone over is so large, you will pardon me if I restrict myself to short practical remarks upon the various heads of the lecture.

The following is the classification which I have long had in my mind, and which I now submit to you:

CLASSIFICATION.

- | | | |
|---|--|------------------------------|
| A—Agents which affect the blood-supply of nervous system. | 1. Agents which increase the blood-supply. | |
| | 2. Agents which diminish the blood-supply. | |
| B—Agents which affect the substance of nervous system. | 1. Agents which increase action of | a, brain.
b, spinal cord. |
| | 2. Agents which diminish action of | a, brain.
b, spinal cord. |
| C—Restoratives and Tonics. | | |
| D—Counter-irritants. | | |
| E—Electricity. | | |
| F—Hygienic means. | | |

CLASS A.

Means which affect the blood-supply.

The indication for affecting the blood-supply of a nerve-centre is sometimes a perfectly correct and logical one.

In practice, we have a certain class of cases in which the symptoms are due to hyperæmia of nerve-centres, and also a certain class in which the symptoms are due to anæmia of nerve-centres.

The vital question is to determine whether the hyperæmia or anæmia be primary or secondary.

Few questions in pathology are of more importance than this, and few have caused such prolonged discussions. This is not the place to examine this matter, and I must limit myself to stating the conclusions to which experience has led me. I believe that true, primary hyperæmia of the brain or spinal cord is a very rare affection, infinitely rarer than the teaching of books would lead us to suppose. In many so-called cases of cerebral congestion there is, I believe, no hyperæmia, but only mal-nutrition, which may be attended by a secondary and passive congestion. In all such cases the leading indication is not to deprive the nervous centre of blood. The effects of anæmia are better known and more commonly observed; and it is an instructive fact to recollect that what we to-day con-

sider as typical of anæmia (epileptic loss of consciousness) was not many years ago looked upon as typical of hyperæmia. In brief, I believe that the indication to diminish the amount of blood circulating in the brain (and spinal cord) is very rarely presented to us practitioners, and that the contrary indication is much more commonly encountered.

The first class of means is subdivided into two sub-classes:

(1) Means which increase the blood-supply.

This sub-class may be still further subdivided as follows:

- (a) Decubitus, or posture.
- (b) Compression of arteries of limbs.
- (c) Stimulants.
- (d) Agents paralyzing the vaso-motor nerves.
- (e) Measures which act by increasing the activity of the nervous centres.

(a)—The amount of blood in the spinal cord can be materially increased by placing the patient upon his back.

The amount of blood in the brain can be materially increased by elevating the legs and arms.

In syncope, therefore, and in all cases where we may suppose that anæmia of the brain is present, the first thing to be done is to place the patient upon his back, and we may, besides, elevate the limbs and trunk. Anæmic patients, who have no positive disease, but who at times feel weak and faint, or suffer from attacks of vertigo, should also have recourse to this means.

(b)—Compression of the arteries of the limbs is a very important and powerful means.

This should be done by tourniquets, as ordinary bands alone will not arrest the circulation carried on through the arteries, but will prevent the return of blood to the body.

This procedure is one which is rarely resorted to, and I would recommend its execution only in extreme cases of cerebral anæmia, as a means next to transfusion. The tourniquets should be applied not simultaneously, in order that you may study the reaction of the heart.

In the days when epileptic seizures were regarded as due to cerebral hyperæmia, compression of the carotids was advised and done to cut short the paroxysms. Insensibility can in this manner be produced in the healthy individual. In epileptics the results obtained were not satisfactory, and the measure is one we now condemn as unphysiological. Besides, in pressing upon the carotid we act upon the vagi, and influence the heart in that way.

(c)—Of the stimulants, alcohol is the best. Preparations of ammonia are employed, but they are less efficient than alcohol. The dose of alcohol in cases of anæmia of the nervous centres is to be gauged only by the degree of reaction observed. In the drowsiness and exhaustion which result from prolonged exposure to cold with or without over-exertion, in cases of loss of blood, brandy will be tolerated in enormous quantities, and the subject saved.

In general terms food is to be regarded as a stimulant, for the general circulation is made more active by taking it. Probably many of you have had an afternoon headache magically cured by dinner.

(d)—Paralyzing the vaso-motor nerves, by producing enlargement of the arteries, is productive of hyperæmia in the arterial district to which the nerves are distributed.

This proposition is demonstrable by experiment upon animals. If we cut the sympathetic nerve in the

* Delivered at the College of Physicians and Surgeons, New York, Feb. 21, 1874.

neck (as was done by Pourfour du Petit in 1712), we obtain a dilatation of all the arteries of the superficial parts of the head, and of all parts of the face, together with contraction of the pupil. As signs of hyperemia, we observe increased size and pulsation of arteries, redness, increased heat, increased secretory action. If we excise the superior cervical ganglion of the sympathetic, we produce hyperemia of the brain itself. In medicine we cannot resort to this radical means of paralyzing the vaso-motor nerves.

Of means to be used for this purpose, the most effectual is inhalation of the nitrite of amyl. The proper dose is from two to five drops.

If the remedy is to be administered by the medical attendant, it needs no preparation; 5 to 10 drops may be poured upon a cloth or handkerchief, and a part or the whole of the quantity allowed to enter the patient's nostrils. In many cases the physician is away during the illness or seizure requiring the use of nitrite of amyl, and the nurse may give it safely, diluted in alcohol, in such a way that a teaspoonful shall hold the proper dose.

The effects of amyl, apparent in a few seconds, consist in hyperemia of the head and face, of increased heart action, and of redness and heat in the remainder of the body sometimes. From the condition of the face and the external parts of the head, and from the sensation of fulness in the eyes and within the head, associated often with giddiness, we infer that there is hyperemia within the cranium as well as without.

One indication for the use of this remedy we find in the condition present at the commencement of an epileptic convulsion. In the very earliest stage, during the occurrence of the aura, or the period preceding the *aura*, which is recognized in some patients, is the proper time to resort to this remedy. If used then, or at the moment the spasm of the vaso-motor nerves commences, indicated by the first signs of failure of consciousness, in many cases the attack can be aborted; in others diminished in severity. Nitrite of amyl has also been used with success in angina pectoris, in asthma, and in various spasmodic affections, involving muscular or vascular parts.

Chloroform has been used in the same manner, but its mode of operation is unknown, and it is much less effectual.

Another means is by over-stimulating the sympathetic nerves, but this means cannot be employed with any great degree of certainty. This is more theoretically than otherwise correct (*vide infra*, sub-class 2, c).

(e)—The means which produce functional hyperemia are exceedingly numerous, embracing as it does all those agents which increase the activity of the nervous centres.

Hyperemia of the nervous system occurs as the result of functional activity in the same manner as it is developed in the various organs of the body as the result of the same cause; such as the congestion present in the stomach and intestines and liver, during digestion, etc. In this connection it is well to remember that it has been shown that increased temperature about the head is developed during exercise of the mental faculties, or by the operation of emotion.

The medicines referred to will be found in class v, sub-class 1.

(2) The second sub-class of a embraces all the means employed to diminish the amount of blood circulating in the nervous centres.

(a) Venesection.

(b) Decubitus.

(c) Compression of veins of the limbs.

(d) Cold.

(e) Those means which stimulate the vaso-motor nerves.

(f) Means which diminish the activity of the nervous centres.

(a)—There can be no doubt that blood-letting, if sufficiently large, will produce cerebral anaemia, for, although physiologists still believe that the quantity of contents of the cranium is invariable, yet they to-day admit that the amount of intra-cranial blood may be reduced; serum taking its place about the vessels and in the sub-arachnoid space. I need hardly tell you that bleeding is out of fashion, and that we nowadays never use it. I would, however, say that with sufficient symptoms of sudden and violent cerebral hyperemia occurring in a subject full-blooded enough not to be injured by the loss, I should bleed without hesitation, by a large opening, and to impending syncope.

It is perhaps right for me to speak here of leeches and wet cups, in order to express my belief that these agents do not relieve hyperemia of deeply placed organs so much by withdrawing blood, as by irritating nerves, and thus acting upon the vaso-motor nerves of the affected parts. These means should therefore be placed in class v, with counter-irritants.

(b)—If the brain is the nervous centre to be affected, the *decubitus* should be with the head raised; or the patient should be placed in a chair with his legs and arms in a pendant position. This latter posture is useful in certain cases (rare, I believe) of insomnia dependent upon true, primary cerebral hyperemia.

In cases of spinal congestion, myelitis, or any affection of the spinal cord attended by congestion, place the patient upon his face. Relief may be secured by permitting the patient to occasionally lie upon the side, but lying upon the back should be almost entirely forbidden.

(c)—Compression of the veins of the limbs may be effected by means of ligatures. Formerly employed in convulsive affections, it has now fallen into almost complete disuse.

(d)—Cold, when used in a proper manner, undoubtedly has the power of diminishing the amount of blood in a part deeper than the skin. It must, however, be applied continuously if any benefit would be derived.

In the treatment of meningitis and all affections in which there is present hyperemia, either primary or secondary, within the cranium, ice should be placed upon the head and at its base for considerable periods of time, carefully watching the effects in order to remove it at once if there is evidence that too much depression is being produced.

The same means may be used with benefit in intra-spinal inflammation and congestions.

Cold is also applied to the back of the neck and upon the spinal column with the object of acting, through the spinal cord, upon the vaso-motor nerves going to distant organs.

A word as to the means of using cold. You will hear Chapman's rubber bags highly recommended, but I suspect that their cleanliness and ease of application are what have caused their fame. It is best to apply the ice in block immediately to the skin, well guarded by cloths to catch the drippings; or pounded ice (with or without salt), enclosed in a cloth or bladder, may be used; or, lastly, the ether spray-douche may be employed.

(e)—The vaso-motor nerves may be directly stimulated by galvanism, causing contraction of the arteries supplied by these nerves, and consequently anaemia of the parts to which these arteries go. This may be ex-

perimentally demonstrated, for the face, by galvanizing the sympathetic in the neck; for the fundus of the eye and the brain, by localizing the action of the current upon the superior cervical ganglion. The positive pole should be applied under the ear, in front of the mastoid process (small electrode), the other electrode be placed upon the fifth cervical vertebra; the current, of from 4 to 8 Stöhrer's cells, allowed to pass for one to two minutes.

Evidence of spasm of the cerebral arteries is obtained in the shape of vertigo developed at the moment of closing and opening the circuit. The vessels of the fundus of the eye have been seen to grow smaller under this application. Anemia of a part of the brain is no doubt the inevitable immediate result of thus irritating the superior cervical ganglion, but a law of physiology stands in the way of our accepting this as a means to be used to meet the indication of diminishing the supply of blood. The law I refer to is that of never-failing relaxation after spasm, of exhaustion after stimulation. This law leads me to believe that after the primary cerebral anemia produced as above described, there is a consequent, equally inevitable relaxation of blood-vessels and hyperemia produced. This is how I would justify the placing of this means, galvanization of vaso-motors, among those which increase the amount of blood in the brain (*vide supra*, sub-class 1, d).

Among medicinal agents, I know of few which will stimulate the vaso-motor nerves, which are not medicines that should be embraced in another class. One exception, perhaps, is ergot.

Some recent observations seem to indicate that ergot diminishes the amount of blood circulating in the spinal cord and in many other tissues. It has been demonstrated that belladonna in small doses will accomplish the same thing. These two remedies, therefore, are quite generally used in the treatment of congestions and inflammations affecting the nervous centres. We are indebted to Dr. Brown-Séquard for their introduction into practice upon correct indications.

(f)—Diminution of the activity of the nervous centres may be brought about by mental and physical rest. By mental rest I understand, not inactivity, but a cessation of the strain, intellectual or emotional, which has acted upon the patient. The merchant or professional man should diminish or cease altogether his work, whether in the way of actual labor or responsibility; he should resort to other occupations and to amusement. On the contrary, the emotional girl, or the insane subject, should be given work, physical if possible, in order to withdraw the attention from the contemplation of delusive sensual or pure emotional subjective creations. The operations of grief, of misery, of concentration in a diseased self, should be remedied by a variety of means (including amusements) which will suggest themselves to you. At all events, please remember that mental rest is not synonymous with inertia or idleness.

Physical rest is of great utility, and has been employed in locomotor ataxia with especial benefit.

Various remedies may be used for the purpose of diminishing the activity of the nervous centres, and these will be referred to in sub-class 2 of the next class, B.

CLASS B.

Means which Affect the Substance of the Nervous Centres.

(1) Agents increasing action of nervous centres.—Excitants.

By nervous excitants I understand such means and

medicines as produce (or can produce) an immediate stimulant effect upon the nervous centres, independently of any corresponding increase in vascularity. The certainty (specificity?) and rapidity of their action distinguish these medicines from tonics.

- | | |
|----------------------------|--|
| (a)—cerebral
excitants. | { Alcohol, embracing wines, brandies, etc.,
Cannabis Indica.
Belladonna, Opium, Ether, etc., Intellection, Emotional Influences. |
| (b)—Spinal
excitants. | { Strychnia, Brucia, Quinia, Cantharides,
Exercise (active and passive). |

A.—CEREBRAL EXCITANTS.

It is very probable that alcohol acts upon the tissue of the brain and superior motor centres, as well as upon the circulation. I have already referred to the dosing of alcoholic drinks, and would only add that for the present purpose small quantities often suffice. In order to secure uniformity in the dosing of alcoholic stimulants, I should be in favor of using diluted alcohol instead of wines or brandy or whiskey. The only obstacles to the adoption of this practice are the prejudice existing against alcohol, and the fact that some stomachs bear wines and beer better than spirit.

Cannabis indica has been used in cases of melancholia and acute dementia, and in various neuralgic states.

Its specific effect is to excite the imagination. A sort of delirium is produced which, in most cases, is not accompanied by absolute unconsciousness, although the patient has the most extraordinary fancies, hallucinations, and delusions. It is this power of stimulating the imagination which has placed it among the remedies to be administered in apathetic cases. The success of the remedy, however, has not quite equalled the anticipations of theory.

In cases of cerebro-spinal mal-nutrition (*migraine*, etc.) its influence is beneficial.

Belladonna and opium are both stimulating to the brain when given in small doses, increasing intellection and producing hallucinations. When given in large doses they produce, besides, an after-effect of depression.

It is only upon some few individuals that this peculiar effect of belladonna is manifested; and many patients can take this remedy for a long time without complaining of any hallucinations or excitation of the imagination.

One of the dangers of administering opium is the temptation to continued indulgence in the use of the remedy for the sake of the intoxication which it produces. I would ask you always to bear this danger in mind, and to consider the responsibility attaching to the giving of opium as not ended until you are satisfied that your patient no longer uses the medicine. After treating a neuralgia, or other painful affection, with opium internally, or with hypodermic injections, you are to withdraw the narcotic very gradually—to wean your patient, as it were. I cannot conceive of a much greater cause of sorrow for a medical man than to have been the cause of the enslaving of a human being by the opium habit.

Ether produces intoxication which is often very violent, when given by inhalation for purposes of anaesthesia. It is not ordinarily employed as a cerebral excitant.

Emotional excitement is not sufficiently employed as a means for affecting the nervous centres. It is seldom applicable where organic disease is present, but is more especially indicated where the mind is absorbed in contemplation of delusions, and in hypochondriacal and hysterical cases.

Cases of hysterical paralysis have been cured by an alarm of fire, or some other immediate danger. The pleasurable emotion of hope is very powerful, and its use makes possible the success of various quackish methods. In legitimate practice we should, I think, make greater use (within the bounds of truthfulness) of the potent emotions of hope and faith.

Many cases of melancholia have been benefited in a remarkable manner by getting them interested in some matter, either of love, or affection, or emulation. There are patients who have a certain amount of dementia, produced by the presence of some convulsive disease, such as epilepsy, chorea, etc. In these cases intellectual exercise is to be recommended and insisted upon; some intellectual excitement should be daily enforced.

R.—SPINAL EXCITANTS.

Nux vomica, strychnia, and brucia are medicines which affect in an almost specific manner the motor parts of the spinal axis, stimulating it primarily. The result of over-doses of these remedies is spasm of muscles supplied by spinal nerves. In small doses these drugs act upon the same parts slowly, and improve their nutrition. The indication for the use of strychnia, etc., is the existence of simple exhaustion of the nervous centres, of spasm due to weakness and anemia, of paralysis (inhibitory or reflex) not due to inflammation of the spinal centre.

We also make use of these remedies in some cases of functional nervous disorders. They are beneficial in cases of chorea and epilepsy, the morbid states grouped together under the name of "spinal irritation." In many of these cases the remedy (strychnia) should be given in the manner long ago pointed out by Brown-Séquard, that is, in doses necessary to obtain its physiological effects.

Bearing in mind that females are much more susceptible to the influence of these drugs than males, you should commence the giving of strychnia by doses of 1-40 or 1-32 gr., increasing rapidly to 1-16 or 1-12 gr. three times a day for adults. There is not the same ratio of susceptibility to the influence of this remedy, with regard to age, as is seen in connection with opium and some other remedies, children bearing large doses well. *Nux vomica* may be administered in 1-4 or 1-3 gr. doses thrice a day, and the doses may be progressively increased.

It is better to use strychnia in solution. If given in pill, you will run the risk of the drug not having been carefully divided in the preparation of the pills; and the additional danger, which is much more likely to happen, that the pills will not be dissolved in the alimentary canal until an accumulation of them has taken place, which will develop results most undesirable. The necessity of using an acid to properly effect a solution of strychnia permits us to use diluted phosphoric acid, which is itself a serviceable remedy in the treatment of nervous affections; or we may use the various acid phosphates which are now offered to us in elegant preparations by druggists.

In cases of paralysis, strychnia may be used hypodermically, with benefit, 1-40 to 1-10 gr. being injected once a day, or once every other day. For this purpose I would recommend Barwell's solution at half strength, 1 minim of which contains 1-50 gr. strychnia.

Quinia sometimes acts in a manner which entitles it to a place in this class of remedies.

There has been considerable doubt as to whether quinia affects the nervous system at all. There are, however, good reasons for believing that the phenomena of intermittent fever are of spinal origin. Quinia

cures all forms of this disease almost with certainty. Another reason for believing that quinia affects the nervous centres is the fact that its administration aggravates spinal disease. According to Brown-Séquard, it acts as a poison to epileptics, and this effect will allow of only one explanation, namely, that the motor centres concerned in the production of the paroxysm are excited and rendered more susceptible by this remedy. Lastly, we have the general tonic effects of quinia, which cannot be denied.

Quinia will also stimulate the cerebrum, as is shown by the fact that intellectual exertion is more easy and free after its use. Dr. W. H. Draper, of this city, has given small doses of the medicine to two well-known clergymen, with the result of restoring their power of extemporaneous speaking.

Cantharides excites the spinal cord, and seems to act more particularly upon its lower portion, manifesting its action by the development of symptoms especially connected with the genito-urinary apparatus. It is useful in cases of bladder paresis, of impotency, or simple genital inertia.

Exercise, both active and passive, is indicated in conditions of paralysis or paresis, or in simple spinal debility. Much of the passive exercise we make use of is obtained by means of electricity, which will be separately considered. Exercise should never be pushed to exhaustion; and I would have you bear in mind that exertion more easily produces exhaustion in the subjects of nervous diseases, and in the insane especially.

Original Communications.

HYDRO-CHLORAL BY THE RECTUM IN THE VOMITING OF PREGNANCY.

By D. B. SIMMONS, M.D.,

CHIEF SURGEON TO KEN HOSPITAL, YOKOHAMA, JAPAN.

WE DO NOT remember having seen hydro-chloral, by the rectum, recommended in the vomiting of pregnancy.

Should this application of it, however, not be new, the results of the following observations may still have their value for or against the conclusions already arrived at.

Aware of the suddenness with which this symptom sometimes ceases, after all hopes of saving the mother, without emptying the uterus, have failed, and that, too, without being able to attribute it to any of the numerous remedies which usually have been tried, *except the last*, we have waited patiently for a third case before venturing a decided opinion as to its value.

Although we saw these cases only in consultation, especial care was taken to obtain their correct histories.

CASE I.—Patient æt. 30; third child. Commenced excessive vomiting during the fifth week of pregnancy, which continued, with the usual intermissions, till the tenth week, when we saw her. For several days previous the nausea and vomiting had been almost constant, both day and night. She had become very much emaciated and unable to sit up, even in bed, not having retained any nourishment on the stomach for several days. All the usual remedies had been tried, such as oxalate of cerium, hydrocyanic acid, hypodermic injections of morphine, etc., but with little benefit.

We suggested the administration by the rectum,

morning and evening, of 30 gr. of hydro-chloral on mucilage, this to be increased if there was no improvement, or if the specific effect of the medicine was not too decided. An amelioration of the symptoms was obtained by the first injection, and a still more satisfactory one followed the administration of the second.

The second day's use of the remedy arrested the vomiting, except at long intervals, and on the third day both nausea and vomiting ceased entirely. There was no return of the symptom. Some nourishment was taken and retained, even on the second day. From this time the patient rapidly gained strength, and was delivered of a healthy child at term.

CASE II.—Patient æt. 32; second child. Excessive vomiting commenced on the fifth week. Saw her at the end of fourth month. During this time there had been frequent periods of four to five days, of comparative freedom from sickness, when nourishment could be taken. For ten days previous to my seeing her, however, she had been unable to take any solid food whatever, and but the smallest quantity in any form. The nausea was constant, and the vomiting very frequent and prolonged. She was very weak and much emaciated. No medicine afforded any decided relief. We advised 30-grain doses of hydro-chloral by the rectum, morning and evening as before. The first portion afforded sensible relief, as in the previous case, to the more distressing symptoms. The administrations on the second day were followed by still more decided results. Still more on the third, and on the fourth the nausea and vomiting had ceased entirely. Nourishment was now taken in moderate quantities, and the patient was soon able to be up again. This case proved more obstinate than the first, as there was a return of the symptoms two or three times, but they were easily controlled by a repetition or two of the injection.

CASE III.—Patient æt. 20. First child. Vomiting in an unusual degree; commenced on the sixth week of pregnancy, and we saw her on the ninth. The history of this case was similar to the preceding. We found the patient very weak and emaciated, and unable to retain food on her stomach of the simplest kind.

The nausea was persistent and the vomiting very harassing. Some of the ordinary remedies had been tried, but to no purpose. We prescribed the hydro-chloral as before, and with the same result. On the third day the nausea and vomiting had ceased; the patient took a fair amount of nourishment, and has had no return of the symptom.

A fourth case presented itself, of a similar character, not a week since. The patient is in her eighth month of pregnancy.

Suddenly excessive vomiting supervened, with inability to retain the least food on the stomach. Decided hysterical symptoms appeared at the same time, showing the vomiting to be undoubtedly of a nervous origin. 30 grs. of hyd. chloral were administered by the rectum, which had the effect of quieting the gastric irritability, so that on a return of the hysterical symptoms some hours after, a dose of 20 grains more, administered by the stomach, was retained without difficulty.

The first three cases we consider as typical of this form of disease. That the relief obtained was due directly to the remedy employed, we have not the slightest doubt.

Should another opportunity offer for a trial of this plan of treatment, we have decided to commence with larger doses, being convinced that a decided impression, produced by the medicine at first, will require its

repetition but two or three times to put an end to the disease, for the time at least.

We believe that hydro-chloral, administered in this manner, will relieve most cases of nervous or sympathetic vomiting, where there is no inflammation especially. Even in strangulated hernia, on theoretical grounds, it ought to act well, not only in checking the vomiting, but in producing relaxation. We should give it a trial also in cholera.

THE ACTION OF QUININE AS A CARDIAC SEDATIVE IN ARRESTING INTERNAL HEMORRHAGE.

By SALVATORE CARO, M.D.,

NEW YORK.

THE effects of the administration of quinine in quieting the action of the heart is pretty well recognized by all who have had their attention directed to the subject. In cases of prolonged and obstinate hemorrhages, where all the ordinary means fail in arresting them, we have, in this peculiar property of quinine, a remedy of which we cannot speak too highly. As illustrations bearing upon this point, I beg leave to present the following cases, premising that their recital in detail is warranted as proving that none of the ordinarily recognized methods of treatment were neglected; and that the use of the quinine was the explanation of the ultimate success in each:

Early in the morning of June 26, 1871, I was hurriedly summoned to attend Thomas Walker, horse-jockey, 28 years old, and of nervo-lymphatic temperament. I found him bleeding profusely from the right nostril. I was informed that he had been struck on the bridge of the nose. Examination revealed a great swelling of the face from the eyebrows to the upper lip, and cyanosis of the external integuments. There was no abrasion of the skin, nor fracture of the nasal bones. Although he had lost an immense quantity of blood during the night, his pulse continued quite full and upwards of 100 per minute. His skin was almost blanched, and the veins could be easily traced, being more than ordinarily full of apparently dark blood. I washed the accumulated blood from his face, and then stuffed the nose with equal parts of tannin and powdered matico leaves; applied (iced) cloths to the bridge of his nose, and gave internally half a grain of opium every two hours. This stopped the bleeding until 6 P.M., when it returned as bad as before. The same remedies were again used, and the opium was increased to three-fourths of a grain.

He rested until 6 A.M. the day following, when the blood reappeared. This time I plugged the nose anteriorly with the same powder on coarse lint. 4 P.M. the bleeding returned, finding its way through the posterior nares into the mouth. In consultation with Dr. J. L. Little, we decided to plug the nose posteriorly, which was done by Bellocq's canula. Ten drops of the tincture of iron were given every four hours. At 8 and 11 o'clock of the same evening respectively, the patient bled from left nostril, but this was arrested by the above powder.

June 28th, 6 A.M.—He bled profusely from both nostrils, particularly the right. I removed the plug, washed the parts with tincture of iron and water, re-applied a larger plug to the right nostril posteriorly, and stuffed the left anteriorly with tannin and alum. In place of iron, thirty drops of tincture of digitalis every two hours were administered, the pulse being

then as full as ever. He was taking plentifully of beef-tea.

June 30th, 1 P.M.—The plugs removed, owing to copious and very offensive discharges, accompanied by painful sensations in the cavity of the nose. Occasional dressings of pulverized persulphate of iron kept the blood from reappearing.

July 2d, 1 P.M.—Blood returned in greater quantity than heretofore. For the third time the nose was plugged posteriorly. Up to this time the loss of blood was estimated at about four pounds. Digitalis was substituted by the fluid extract of veratrum, three drops every two hours.

July 3d, 1 P.M.—Hemorrhage returning, plugs saturated with liquor ferri persulphatis arrested it. 3 P.M. I was again summoned to find my patient in syncope; pulse very feeble. Epistaxis arrested, but blood oozing from the right ear. Through a glass tube, I blew in powdered tannin and iron, and ordered bladders of ice to be applied to the head, round the neck, and all over the thorax; also a tablespoonful of whiskey every two hours, with beef-tea and cream, and discontinued the veratrum. He rallied a little, although bleeding every three or four hours in quantities of four to six ounces, which was checked by washings of water and liquor ferri persulphatis.

July 9th, 9½ A.M.—There was bleeding from right nostril about four pounds, and from the right ear a tablespoonful. This was easily stopped by the iron wash, and the ears with powdered tannin and iron. He was then taking internally every two hours dr. doses of the fluid extract of the Peruvian bark. 7½ P.M. Bled about three pounds from right nostril. July 10th, 6 A.M. Bled about four pounds; stopped as above. 4 P.M. Bleeding returned as freely as ever, and arrested as before.

July 11th, 5 A.M.—Bleeding returned, and was arrested by the same wash. Teaspoonful doses of fluid extract of ergot and twenty drops of the elixir of vitriol were given alternately every two hours. 6 P.M. Bleeding, but stopped by the same remedies. July 12th, 4 A.M. Bleeding returned with more alarming symptoms than heretofore from both nostrils and right ear. Plugging in this case had not the least desired effect, but rather a tendency to the return of the hemorrhage, by the constant applying and removing of which my patient not only complained, but in my opinion the bleeding was increased by tearing off the newly formed clots.

So far, all remedies failing and the life of my patient momentarily threatened, I determined to abandon the above treatment. It may be proper to state that during this time I discovered him suffering from palpitation of the heart. Examination of the thorax revealed a very distinct and loud cardiac murmur with mitral regurgitation, with hypertrophy and quick action of the heart. The heart measured seven and a half inches in length and five inches in width. On watching him for a few minutes before the return of epistaxis, I could distinctly see the precordial region swell, the heart become tumultuous in action, and the blood propelled to the carotid arteries. The jugular veins became turgid, and the neck and face assumed a cyanotic hue, which condition was immediately followed by epistaxis. Digital pressure upon the carotid and facial artery had very often modified the velocity of the hemorrhage. Such being the condition of my patient, I removed all dressings except the ice over the thorax, washed the nose with glycerine and carbolic acid, and directed my attention to the condition of the heart.

July 12th, 4 P.M., the fifteenth day of the epistaxis,

I prescribed two grains of quinine every two hours until July 13th, 5 P.M., the patient taking in all twenty-five grains. No ill effects were produced, and the hemorrhage was totally arrested.

Finding the pulse considerably reduced, I decreased the quantity of quinine to one grain every two hours, until the 14th, 6 A.M., using but six grains in twelve hours. This did not prove so beneficial, as he had a return of hemorrhage at 7 A.M. I was compelled to increase the quinine to three grains every hour, which arrested the blood as before; seventy-five grains were thus used in twenty-five hours.

July 15th, 10 A.M.—Hemorrhage returning with greater severity, I increased the dose to five grains every hour. In twelve hours he thus consumed sixty grains. 10 P.M. of the same day, having another alarming attack of hemorrhage, I determined to give ten-grain doses every hour until the 17th, 12 M., using thus two hundred and sixty grains in the space of twenty-six hours. By this time the hemorrhage having ceased, and the heart appearing calm and regular, I ordered the ice removed, my patient washed, and permitted to walk about the room.

From this date until the 23d, 12 M., quinine was reduced to two grains every three hours, consuming in these doses ninety grains in one hundred and forty-four hours.

From July 12th to the 23d five hundred and twenty-one grains of quinine were consumed.

The principal noticeable symptom was a decrease of heat, particularly in the hands and feet. In the cavity of the axilla, the thermometer, previous to the use of quinine, marked 103° F., even after profuse hemorrhage, but after small doses it would fall to 99° F., rising when the quinine was losing its effects. At ten-grain doses the thermometer in the cavity of the axilla marked 94½° F.; 95° F. in the mouth and anus; 93° F. in the inguinal region, with the leg flexed over the abdomen and between the legs on the perineal region; 90° F. in the palm of the hand; 91° F. at the flexion of the forearm; 88° F. between the toes, and 89° F. in the popliteal region. This extreme algid state lasted about two hours, and on removing the ice from the body heat returned. He never complained of feeling cold, but insisted upon keeping his feet out of the window. When the quinine was decreased, heat gradually returned, never reaching 99° F.

All mechanical and therapeutical agents being suspended, and epistaxis arrested only by the internal use of sulphate of quinine, I may justly give to this drug the name of styptic or general sedative of the cardiac organ. I have had occasion to observe the sedative action of quinine on hypertrophy of the heart producing copious hemoptysis. Where all the well-known remedies used under the best form and advice have failed, quinine alone, in five-grain doses every four hours, has quieted the heart, arrested the hemoptysis, and given temporary relief.

In the three following cases, quinine was the only remedy to arrest hemorrhage:—

Mr. P., aged 38, robust, sanguine temperament, Nov. 24th, 1873, was suddenly seized with profuse hemoptysis. Iron, ergot, and elixir of vitriol failing, five grains of sulphate of quinine every hour instantly arrested it. The use of five grains of quinine three times a day was continued in order to maintain the pulse at about seventy-five per minute.

Mrs. D., a very robust and sanguineous temperament, Dec. 8th, 1873, upon lifting a heavy box was seized with hemoptysis, which resisted all known remedies for three days, yielding to five grains of quinine every hour.

Miss S., aged 28, nervous temperament, for the past three springs has been troubled with bronchorrhagia, of very little account. On the 3d of March, 1874, the usual affection returned in a more alarming manner, and after the failure of the old remedies, she was relieved instantly by five grains of quinine as above.

The amount of quinine used in the first case was fifteen grains; in the second, twenty-five grains, and twenty in the third case, besides the continuation of five grains three times a day for three days. In uterine hemorrhages quinine has proved equally successful; but the space allowed me in this paper being limited, prevents me from enlarging upon the subject. The following experiments and views of others may, however, elucidate the subject.

Injecting a solution of quinine (eight grains) under the skin of the right hind leg of a small dog (95° F. in a.u.), the first observable symptom was the lowering of the temperature four degrees. I immediately opened the chest, found the heart relaxed, the cardiac impulse weakened, and the blood less rapid and voluminous. I could also see the arteries undergo a change of volume; the capillaries particularly appeared as if they were empty and atrophied. In the case of a second dog of the same size, fifteen grains were injected; temperature lowered eight degrees, and the animal died shortly after with paralysis of the heart. On opening the chest, the heart was found completely relaxed, as soft as a rag, and with scarcely any blood in the left ventricle. Operating upon a third dog, three grains were injected. Temperature rose one degree, and the pulse became more frequent. On opening the chest the heart was found tense and beating rapidly. The blood being microscopically examined before the use of quinine, the corpuscles were found thin and running about; when cinchonized, were shrunken in various irregular forms; indented or jagged at the edges, and very much altered in shape.

The lowering of the temperature after the use of quinine has been ascertained by Lewizky, Ranke, Kerner, Shulte, Zuntz and Sharenbrich. They are of opinion that the drug acts upon the intercardiac nerves, producing an irritation of the periphric extremity of the valves, paralyzing the periphric extremity of the motor nerves of the heart and the motor muscular system of the same, decreasing its activity and producing diminution of the blood-pressure and peripheral heat.

Cohnheim says that quinine has the power of arresting the motion of the white corpuscles of the blood, preventing the development of animal heat, and reducing blood pressure. Bintlz thinks that quinine in high doses paralyzes the action of the heart and arrests the motion of the white blood-corpuscles, by the diminution of the oxidizing power of the red corpuscles, and in small doses acts like a tonic by increasing the cardiac action. These observations have been corroborated by Heller and Zahn. Traube opines that the relaxed condition of the heart is produced by the stimulating action of the quinine upon the vagus.

643 LEXINGTON AVENUE, N. Y.

CREMATION.—The proposal that cremation should be substituted for burial has met (a correspondent of the *Pall Mall Gazette* writes) with a most favorable, it may be said enthusiastic, reception in Switzerland. A meeting, held recently at Zurich, for the discussion of the scheme, was crowded, and numbers had to be sent away from the doors because there was no more room. Professor Kinkel was the principal speaker, and in order not to disappoint those who could not hear, the addresses were published.—*Br. Med. Jour.*

CONTRIBUTION TO LARYNGEAL PATHOLOGY.

SINGULAR CAUSE OF UNILATERAL PARESIS OF THE VOCAL CORD.

By EDGAR HOLDEN, A.M., M.D.,

NEWARK, N. J.

Miss —, æt. 26, a tall, dark-complexioned lady, a teacher by profession, and one of a family of marked tuberculous tendencies, was brought by her physician for laryngoscopic treatment in November, 1871. Acutely sensitive to the suggestion afforded by a cough, she had been for several months alarmed by frequent colds, accompanied by hoarseness, and even complete aphonia. Indeed, this condition had existed for nearly a year, and a short, harassing cough, loss of appetite, and occasional fever had given rise to the gravest apprehensions.

Examination of the lungs exhibited considerable bronchial irritation, and a small spot of consolidation at the apex of the right lung, without evidence of softening. Temperature, 100; pulse, 90, regular and compressible; aphonia complete; cough harassing, short, and ineffectual. The larynx under the light was found intensely congested, and so tumefied that the vocal bands were seen with difficulty. The aryteno-epiglottic folds were also swollen, although not prominently, nor was the swelling so distinctly characteristic as in the early stages of phthisis. The capitule Santorini were each surmounted by a little spot of erosion, evidently quite superficial. Under local treatment, within a fortnight, much of the distress had disappeared.

It is worthy of remark that after the second application (which was made with a brush, and was Marcet's solution of iodine and iodide of potassium in olive oil), the voice immediately returned, lasting about an hour, and from that time it was always possible to restore it instantly by a proper application, although it was retained but a short time at each brushing.

In brief, after the cure of the long-standing laryngitis and the disappearance of the cough, the voice would not remain fixed, and after the use of various tonics a change of air proved immediately successful. Relapse, however, followed return to the city, and rest at home from her labors as teacher made but little difference in the symptoms. It was repeatedly necessary to combat the tendency to inflammation, which recurred under perplexing circumstances, and without apparent cause.

In March, 1872, whether overlooked or not in previous examinations, the right vocal cord was seen to come up lazily into line, and fall back without vibration. There was now not a continuous aphonia, but occasional attacks with intervals of two or three days.

This condition gave a key to the difficulty. There was evidently paralysis of the adductors of the right cord, and the application of the faradic current with Mackenzie's electrode to the muscles confirmed the opinion. Stryclina was given in gradually increasing dose, using a two-grain solution, beginning with ten minims (one twenty-fourth gr.), three times daily, with directions to increase one drop each day, until stiffness or cramp in either the neck or limbs was experienced. So long as the patient was under its influence there was no aphonia, and she gained flesh and strength, and in fact was better in general health than for several years. It was, however, found necessary to increase the dose steadily, as trouble was threatened; and during my absence from town for a few weeks the patient attain-

ed the enormous dose of a dessertspoonful (probably not more than one and one-half drachms, yet at least $\frac{1}{2}$ of a grain three times daily) without any unpleasant symptoms; in fact, there followed only a pleasurable exhilaration. Upon reducing the dose the aphonia returned, and both the direct and induced galvanic current gave but temporary relief. A battery of alternate plates of zinc and copper was adapted to the external aspect of the larynx with better success, and either this or a Pulvermacher's chain improved the voice, *while worn*, but it totally disappeared and hyperemia quickly supervened when they were laid aside.

This paralysis was strictly local, and with the single exception of a drawing of the uvula toward the affected side for a short period, no other impairment of motion or sensation occurred.

Pain in the larynx, which was not very infrequent, always yielded at once to either the Franklinic, direct or induced galvanic current, and it seemed to matter but little whether passed from the hyoid fossa to the anterior surface of the thyroid, or internally by means of the intra-laryngeal electrode.

These attacks of pain were, however, only occasional.

Aphonia, whether coming suddenly or by slow degrees, was always accompanied from its outset with a singular general weakness, such as is not very uncommon in even slight laryngeal diseases.

In searching for the key to this singularly localized trouble, one feature escaped attention, viz., the fact that whatever the change of air was on any occasion—that is, whether to a near or remote point—the result was always the same, *the voice and strength returned on the second day*, provided in each case the hyperemia had not become excessive. But after reviewing the possible causes of this unilateral paralysis, the weakness of the tensors, suggestive of a tubercular diathesis, the development of some cerebral disease, the pressure of some morbid growth upon the pneumogastric or its motor branch, the presence of some blood-poison, as from diphtheria, etc., the fact mentioned suggested at once the cause, viz., some toxic agent in the locality of her residence; and that this agent was the vapor from a neighboring patent-leather or enamelled cloth factory was made apparent when it was found that, after an absence from home, an immediate relapse followed return *only* if the manufactory was running, but not otherwise. Farther than this; however long-continued or perfect had been the restoration of the voice, one night's sleep at home often sufficed to destroy it altogether.

Acting upon this belief, recovery has been most satisfactory.

It might be added for the information of those unfamiliar with the branch of manufacture referred to, that upon damp days and at certain seasons of the year a peculiar suffocating sensation is experienced by strangers when in the vicinity of the factories, quite similar to that which occurs upon inhaling pure nitrogen, but that no tendencies have as yet been discovered in the emanations to develop disease.

[NOTE.—We gladly publish the foregoing case, which calls definite attention to an important subject, viz., injurious effects of emanations from factories near dwelling-houses—but its interest does not lie in singularity, as the author supposes. On the contrary, paralysis of the vocal bands is very frequently due to irritation and inflammation of the mucous membrane, and, we fear, this frequently depends on some such cause as in this case.—ED.]

THE ANNALES DE GYNÉCOLOGIE is a new French periodical, edited by MM. Gullard, Pajot, and Courty, with Dr. Leblond for its Editor-in-Chief.

FRACTURE OF THE PETROUS PORTION OF THE TEMPORAL BONE, WITH RECOVERY.

By JOHN Q. ADAMS, M.D.,

CARMEL, N. Y.

The following case is reported as a contribution to those rare fractures at the base of the skull which are usually regarded as fatal:—

Mrs. T—, American, healthy, aged 52 years, weight 200 pounds, was thrown from her carriage, striking upon the head. This occurred on the 25th September, 1873. Half an hour afterwards she was unconscious, nearly pulseless, surface pale and cold, pupils dilated, hemorrhage from right ear profuse. There was a puffy tumor over the parietal bone of the right side; no solution of continuity in the soft parts. 11 P.M., vomiting came on an hour after the injury; partial reaction has come on, but consciousness has not returned.

26th, 7 A.M.—Has been in a deep stupor most of the night; vomited occasionally; hemorrhage from the ear continues; pupils a little dilated, answering the light; skin hot, face flush, pulse 84. 12 M., pulse 64; pupils contracted, influenced by light; breathing with a peculiar puffy, blowing expiration, but not stertorous. 11 P.M., consciousness returning; complaints of nausea and headache. Ordered to take pil. cathart., c. No. iv.

27th, 7 A.M.—Had two stools during the night; nausea less; complaints of the headache; wakes occasionally without being aroused; recognizes friends, but cannot call names; ideas confused. 10 P.M., collects names with considerable effort.

28th, 7 A.M.—Slept well; begins to worry about her household; discharge from the ear, which has continued from the first, and apparently bloody, is now becoming very perceptibly serous; intellect sluggish; no nausea. Ordered sal. Rochelle $\frac{1}{2}$ i. 9 P.M., had two stools. Slept some. Pulse 60; skin natural.

29th, 5 A.M.—Slept well during the night; discharge from the ear profuse—clear, limpid serum. The quantity discharged during the last twenty-four hours was from two to three ounces. 7 P.M., right side of face paralyzed, considerable swelling, and extreme tenderness; unable to close the eyelid; vision dim and wavy; deglutition difficult. Noticed a peculiarity of the countenance yesterday, but waited developments without noting. Headache confined to right side; no nausea; pupil of right eye larger than the left; both answer light. Pulse 76, moderately full and hard. Ordered tinct. aconite gtt. iv. every four hours; poultice the face. 9 P.M., pulse 64, tongue slightly coated; temperature good; serous discharge from the ear profuse all day, becoming very little colored—no diminution in quantity. Asks for food, but when it is brought her dreads to partake of it, and sets it aside, complaining of dryness and stiffness of the fauces.

Oct. 1st, 10 A.M.—Discharge from the ear more profuse and more colored; otherwise head and face symptoms the same; pulse 56; tongue clean and moist. Discontinue the aconite, poultice the face, syringe the ear with soap and water. Sal. Rochelle, $\frac{1}{2}$ ss.

2d, 9 P.M.—Bowels moved twice to-day; vision is improving; pupil of right eye still dilated; hears a little with the right ear; ear discharging freely a bloody serum. Pulse 68, soft; skin natural, tongue clean.

7th.—Discharge from the ear nearly done; paralysis of the face and eyelid unchanged; face less swollen

and less tender; deglutition improving and appetite fair; vision nearly restored; sleeps well; walks about the house; headache gone. Pulse 64; bowels require laxatives.

11th. Symptoms as at last writing, except complaints of pain in the back, and extending down the thighs. Regulate bowels, and apply rubefacient liniment to the spine. Left her hotel at 2 P.M. to ride fifteen miles.

Nov. 6th.—Paralysis and general condition improving; complains of occasional headaches and strange sounds in the ear; able to attend to her usual household duties.

Jan. 4th, 1874.—She writes that she is as well as she ever was, except the impaired hearing and occasional pain in the ear, which are both improving slowly.

The most important symptoms in this case are the serous discharge from the ear, the hemorrhage and the paralysis. The serous discharge from the ear was of all the most diagnostic of fracture of the base of the skull. This discharge gradually took the place of the hemorrhage; on the third day after the injury becoming very apparent, and on the fourth perfectly clear, and amounting to two ounces and perhaps three in the twenty-four hours. On the evening of the fifth day the discharge again became tinged with blood. From this time it continued, gradually diminishing in quantity and color, until the thirteenth, when it ceased altogether. The origin of this serous fluid is now very generally believed to be from within the arachnoid membrane, and hence the cephalo-spinal fluid. This fluid could not be discharged through the ear without fracture of the petrous portion of the temporal bone and laceration of the arachnoid membrane. The point at which this membrane would be most likely to be ruptured is in the process which is thrown off as a sheath or cul-de-sac upon the auditory nerve or portion of the seventh pair as it enters the meatus auditorius internus. Still, there has been another symptom coexisting with the serous discharge, which would, I think, render it very probable that the rupture of the arachnoid was more extensive than merely across the cul-de-sac covering the auditory nerve, and that is the profuse and long-continued hemorrhage. If we consider that the rupture of the arachnoid was confined to this process, we must also suppose that the hemorrhage was from the auditory artery accompanying the nerve, which would have been scarcely possible when we take into account the extent of the hemorrhage. The hemorrhage must have amounted, I think, to nearly a quart during the first twenty-four hours. It would seem, therefore, more likely that the hemorrhage came from some larger vessel than the auditory artery. Of course it is not possible to know precisely where it did arise, but from the position of the lateral sinus, it would not be very far-fetched to suppose that it came from this vessel or some of the large veins leading to it. The lateral sinus is situated on the internal surface of the mastoid portion of this bone—the temporal—in close proximity to the base of the petrous cone and directly opposite the tympanum. A fissure through the thin shell of bone overlaying the tympanum, rupture of the arachnoid and walls of the sinus or some of its tributaries, would account more satisfactorily for the existing symptoms. The extent of the hemorrhage, and more especially its duration, is another diagnostic sign of fracture of the base of the skull. The membrana tympani must, of necessity, have been lacerated.

Next, the paralysis. This occurred in the muscles of the face and the eyelid of the right side, the side corresponding to the injury as indicated by the other symptoms. It appeared on the fourth day after the

injury, and therefore probably was not a direct and primary result, but rather the result of inflammatory action affecting the facial nerve. This last theory would be strengthened by the fact that there occurred with the paralysis swelling and tenderness of the whole right side of the face. But the paralysis was not confined to those parts supplied by the facial nerve. The muscles of deglutition as well as sensation in the mucous membrane of the fauces, suffered to some extent, though only partially palsied, and only for seven or eight days. Was the lesion producing the paralysis within the cranium or external to it? In the case of the facial paralysis, I should be inclined to the external view of the question, that of injury to the peripheral branches of the nerve by inflammation and swelling. In the case of the affection of the fauces and larynx, the opposite theory would seem to be true, as there was no perceptible swelling of the fauces, nothing abnormal to the eye except slight increased vascularity and dryness of the mucous membrane. Prof. Gross, in speaking of paralysis of the palate and uvula, says that it only occurs when the injury that gives rise to it is within the cranium and close to the petrous portion of the temporal bone. He also locates the injury in the filaments of the sphenopalatine ganglion. This ganglion, the sphenopalatine, or Meckel's, is situated in the sphenomaxillary fossa, and sends several branches to the palate, uvula, tonsils, and mucous membrane of the fauces, while its communicating branches are the vidian, carotid, and petrosal branches, which are distributed in the immediate vicinity of the petrous portion of the temporal bone.

There is one other nerve that may have been disabled in this case, the glosso-pharyngeal. This nerve, one of the eighth pair, arises with the facial and near the auditory, from the groove between the corpus olivare and restiforme, and emerges from the skull through the foramen lacerum posterius, and is distributed to the mucous membrane of the fauces, tonsils, and stylo-pharyngeus muscle, which is the middle constrictor of the pharynx. This nerve, from its origin to the ganglion of Andersch, situated in the jugula fossa, is purely a sensitive nerve. After leaving this ganglion, it is supplied with branches from the facial and spinal accessory, both of which are motor nerves, thus changing the glosso-pharyngeal into a mixed nerve, and accounting for the impaired motor and sensitive forces manifest in this case. The proximity of origin of these three nerves, the auditory, facial, and glosso-pharyngeal, and their distribution corresponding to the parts paralyzed, as they do, would seem to offer strong proof that the glosso-pharyngeal suffered injury with the others.

Progress of Medical Science.

THE MUCOUS MEMBRANE OF THE LARYNX.—M. P. Coigne publishes in the January number of the *Archives de Physiologie* some researches on the mucous membrane of the larynx which are of much interest. He notices, first, the existence of a sub-epithelial, reticulated layer, analogous to the lymphoid tissue beneath the mucous membrane of the small intestine; also certain lymphoid bodies, which have hitherto been unknown, similar to the closed follicles of the small intestine. Great as may be the anatomical interest of this discovery, its pathological importance is greater, for the presence of these bodies may account for the ulcerations of the larynx which occur during the course of pyrexias, such as typhoid fever. Again, M. Coigne has observed on the

free border of the true vocal cords certain papillæ, containing vascular loops, and probably a nervous twig also. With the greater development of these papillæ on the anterior half of the cord may be associated the greater frequency of papillomatous growths at this part of the larynx. Besides the above, the author describes also some follicular glands whose ducts take an oblique direction so as to converge towards the free edges of the true vocal cords, with the manifest object of moistening a part liable to become dry. The closed lymphoid glands are situated chiefly beneath the mucous membrane of the false vocal cords and the sacculus laryngis. Further, at the free border of both true and false vocal cords the epithelium ceases to be ciliated and becomes squamous in character.

TREATMENT OF RICKETY DEFORMITIES OF THE LEGS BY OPERATION.—At the meeting of the Royal Med. and Chir. Society, on Jan. 27 (*The Doctor*), Mr. Howard Marsh gave an account of four cases of rickety deformity of the legs which he had treated by operation. In two of them the curvature was outwards, in one outwards and forwards, and in one almost directly forwards. In the first three cases a tendon knife was passed down to the tibia, where the concavity of the curve was greatest, and the periosteum was divided transversely. A fine saw was next introduced and the bone partially divided, and then, by a somewhat suddenly applied force, snapped across; the fibula was either bent or broken, and in one of the operations the tendo-Achillis was cut.

In the two cases in which the curvature was outwards the legs are now straight; in the boy whose curvature was outwards and forwards, and in whom the treatment was interrupted by an attack of scarlet-fever, the deformity, although much diminished, is not wholly removed. In none of the patients was the operation followed by any serious symptom, and, except in the boy who had scarlet-fever, convalescence was complete in about a month. In him it was complete in about six weeks.

In the fourth case, in which the bones of the leg were curved almost directly forwards, and in which the deformity was so extreme that the boy could walk only a few steps at a time, a wedge of bone was taken out of the tibia with a chain-saw, the tendo-Achillis was cut, and the fibula broken in one leg and cut with bone-forceps in the other. These operations were not followed by any dangerous symptoms, but small disks of bone became necrosed and were slowly separated from the cut ends of the tibia. Union was firm in one leg in three months; in the other, in which it was much delayed by the tedious separation of necrosed bone, in six months. The legs are now straight and the boy walks without impediment.

RELATION OF RENAL APOPLEXY WITH CEREBRAL HEMORRHAGE.—Dr. Augustus Ollivier remarks that the influence of chronic affection of the kidneys on the production of cerebral hemorrhage is well known, but in the present essay he proposes to consider the converse fact, namely, the relation of cerebral hemorrhage on the production of certain renal lesions. Among the cases of this nature which have fallen under his observation are the following:—1. A man aged 74, attacked with apoplexy, with right hemiplegia of the limbs and face. In twenty minutes after the attack the urine was found to have become albuminous; death took place on the fourth day. On post-mortem examination effusion of blood was found to have occurred under the meninges, and a clot had formed under the left optic thalamus and corpus striatum, which had burst into the corresponding ventricle and had made its

way into the middle ventricle and the opposite lateral ventricle. The cerebral peduncles, cerebellum, pons, and medulla oblongata were healthy. Both kidneys, but especially the right, were found to be congested. 2. An attack of apoplexy in a man aged sixty-eight, with hemiplegia of motion and sensation on the right side; ten minutes after, coma. The urine was normal up to the time of the appearance of the coma, but then began to contain albumen. Death occurred in the course of nine hours. The autopsy showed a large hemorrhage into the white substance of the left cerebral hemisphere, which had burst into the ventricles, and even entered the upper part of the left aqueduct of Sylvius; both kidneys were congested, the right highly so, and with an echymotic spot upon it. M. Ollivier reports several other similar cases. He then proceeds to give the details of numerous experiments he has recently performed on rabbits, showing, in accordance with the statements of Bernard, Brown-Séquard, and others, that puncture of the floor of the fourth ventricle is almost constantly followed by the appearance of albumen in the urine. The cause of this is not, however, quite clear; some, with Schiff, considering it to be due to paralysis of the vaso-motor nerves; others, with Brown-Séquard, to be due to spasm of the veins, or of both arteries and veins, causing engorgement and rupture of the capillaries. M. Ollivier, in conclusion, points out that albuminuria of cerebral origin is of more frequent occurrence than is generally admitted, but that our present knowledge does not enable us, from the existence of albuminuria in cases of cerebral hemorrhage, to localize exactly the seat of lesion.

At the same time, when the symptoms of lesion of the medulla oblongata are deficient in an apoplectic patient, it may be said that the presence of albumen in the urine indicates either a hemorrhage situated at the base of the brain, or an extensive hemorrhage elsewhere, exerting compression on the base. In all instances it must be regarded as a very serious symptom.—*Archives Gén. de Méd.*—*The Practitioner*.

THE ACTION OF PURGATIVES.—M. Vulpian has completed some new experiments which confirm the results of MM. Legros and Onimus (*Recherches Expérimentales sur les Mouvements de l'Intestin*) as well as others obtained by M. Benoit, and reported by him in the *Courrier Médical*. Vulpian concludes that sulphate of magnesia and other saline purgatives produce a real intestinal catarrh, by which large quantities of liquid are made to transude into the canal, though a portion is absorbed and removed by the kidney. For this reason these substances are contra-indicated in the vesical catarrh of the aged or in phosphatic gravel, which they would augment. Salines do not increase peristaltic action; but jalap, according to these experiments, did increase this movement as well as produce intestinal catarrh, chiefly of the larger bowel. Here, then, a distinction is furnished between these purgatives.—*The Doctor*, April.

MICROSCOPIC APPEARANCES OF THE BLOOD AND URINE WHICH CONTRAINDICATE REMOVAL OF MELANOTIC TUMORS.—Besides other evidences which may exist of disease of the viscera, M. Nepveu claims that the conditions of the blood and urine are important in determining the propriety of undertaking an operation for the removal of melanotic tumors. In the blood, he says, the leucocytes are increased in number: fifteen, twenty, even forty of them being distinguishable in the field of a microscope, with a No. 3 ocular and 7 objective of Hartnack. They are, moreover, filled with dark granules. The serum presents reddish-brown granules and flexible casts without consistence, and

granular, resembling hyaline casts, and appearing to be derived from the capillaries; moreover, the red globules, when seen *en masse*, have a sepia tint more or less marked.

The urine is rather dark in color, and the addition to it of nitric acid or bichromate of potash gives it a darker tint. Examined under the microscope, the deposit shows cylindrical casts, resembling those of albuminuria; or irregular masses of brownish granules. If the urine is evaporated upon a glass dish, grayish granules surrounded by variously formed crystals are apparent.—*La Tribune Méd.*

TREATMENT OF TRICHIASIS.—M. Menu describes a new operation for the relief of trichiasis, which consists in making an incision parallel to the border of the lid, at some distance from its edge, and through the whole thickness of the skin. The fasciculi of the orbicularis exposed on reflecting the integument upwards, are excised, and the tarsal cartilage is laid bare. The flap containing the roots of the cilia is now dissected back as far as to the edge of the lid, which is not injured. A thread is passed, by means of a curved needle, through the suspensory ligament of the tarsus, then under the inferior flap as far as to the free border of the lid, at which point it issues on the level of the cilia, and the loop is tied. This is done at several points, and the ends of the threads are brought up over the forehead, and fixed by a strip of plaster.

THE OPERATION OF REPOSITO CILIORUM FOR TRICHIASIS.—This operation—recommended by Celsus—has again been brought to the attention of the profession by Argyll Robertson, M.D., who writes to the *Edinburgh Medical Journal* of May. Few text-books make any mention of this simple method, and its introduction, some twelve years since, is due to Dr. Snellen, of Utrecht. The following is the method of operating: A very fine curved needle has the two extremities of a very fine waxed silk ligature (or hair, as Celsus directs) passed through its eye. The needle, being firmly grasped by suitable forceps, is then passed through a narrow fold of skin, at the very margin of the lid, close to one of the inverted eye-lashes. The point of introduction should be external to the point of emergence of the eyelash, but as close to it as possible; and the needle should be brought out after passing through about $\frac{3}{4}$ " or 1" under the skin. The needle and ligature should be drawn through until a small loop alone remains, when, by means of a fine pair of forceps, the eyelash is passed through the loop. Traction is then made on the ligature, and the loop with the entangled eyelash is drawn through the tunnel in the skin.

A METHOD OF TREATING TINEA TONSURANS.—Dr. Edgar A. Browne, writing to *The Practitioner* of May, recommends the following method of treatment as requiring no attention on the part of a nurse or parent, and needing only to be renewed at intervals of three or four days: "A margin of healthy hair is to be cut quite short or shaved round the patch. A brisk rubbing with the oleum picis rect., or some similar hydrocarbon, is the next stage, and the reddened and saturated patch is to be thickly dusted with a powder composed of tannin, iodine, and gum arabic. This is to be moistened with a few drops of the oil, and gently but firmly pressed into the skin with the end of a small cork. Repeat the process till the whole patch is covered with a layer of paste about an inch thick, and then allow it to dry. The firm, hard scab thus formed may be left undisturbed for three or four days, when it should be moistened, scraped off, and reapplied.

SULPHATES PRODUCTIVE OF GOITRE.—In a communication to the French Academy of Sciences, M. Bergeret points out the influence of the sulphates in the production of goitre. He states that before the year 1835 all the inhabitants of Saxon in the Valois were either goitrous or cretins. They then drank water derived from a bank of gypsum, which on analysis was found to furnish one grain of sulphate of lime per litre, besides some sulphate of magnesia. But in 1835 the potable water was derived from a spot situated far above the bank of plaster; and since then, according to M. Bergeret, goitre has much diminished, the children are no longer subject to it, and before long the disease will probably have disappeared. He also makes the somewhat singular statement, that under the conditions of excessive work a man has circulating in his blood an abnormal amount of sulphates, absolutely the same as if he had drank water loaded with gypsum; in support of which statement he cites various experiments, which appear to leave no doubt as to its correctness.

RÖTHLEIN, OR GERMAN MEASLES.—Dr. Robert Living, in a clinical lecture on this affection, records four cases, and then proceeds to make the following remarks: 1. The premonitory fever in German measles is generally mild, and resembles, in many subjects, though not in duration, that of common measles. There are more or less pain in the limbs, slight shivering, sore-throat, and often, though by no means always, coryza, redness of the conjunctiva, and sneezing. The characteristic feature of it, however, is its duration, which is seldom more than twenty-four hours, whereas in ordinary measles it is from three to four days. 2. The character of the eruption when it first appears is almost always described as "measly," that is, in small reddish patches. In the first instance the rash consists of small rounded collections of minute red papules, which after a time coalesce and form large irregular patches, just as in measles, but with apparently less tendency to become of a horse-shoe or crescentic shape. After a time the patches may all unite, and then the skin becomes to the naked eye of a uniform red color, closely resembling that of scarlet fever. The rash lasts longer than the rash of either measles or scarlet fever—from four to ten days. Its disappearance is followed by a desquamation of branny scales, though this is but slight in mild cases. 3. Among the most constant symptoms of this fever is the persistent, though not generally severe sore-throat. The tonsils are red and swollen, and remain in that state usually for some days after the rash has faded; indeed, the sore-throat is often the last symptom to disappear. Unlike that often associated with scarlet fever, it rarely leads to ulceration. 4. The presence of albuminuria is of not unfrequent occurrence, and occasionally leads to acute dropsy. 5. The disease propagates itself, and never leads to the production of either scarlet fever or measles in others, which is conclusive against the idea of its being a mild type of either. 6. It gives no protection to either measles or scarlet fever, nor do these diseases give any protection to those exposed to German measles. The existence of this disease, perhaps, accounts for some supposed errors of diagnosis, where a patient, said by the first practitioner who sees him to be suffering from measles, is pronounced by a second, under whose notice he comes at a later period, to be suffering from a slight attack of scarlatina.—*The Lancet*.

THE EFFECT OF BITCHES' MILK UPON RACHITIC INFANTS.—A curious fact was mentioned by Dr. Parnard at the late meeting of the French Society for the Protection of Infant Life, and is reported in the *Journal*

de Médecine et de Chirurgie, of March. In the Commune of the Drôme, at Montbrun-les-Bains, the women are in the custom of protracting the nursing of their children until the age of two and a half to three years, and all women who lose their nursing before this period has arrived substitute a young puppy. Now, these pups become rapidly rachitic and remain deformed, unless they are returned in good season to the milk of their mothers. This fact is well known to many physicians. Mr. Bernard conceived the idea of subjecting an infant, twenty-six months of age and exceedingly rachitic, to the use of the milk of a bitch. After having employed in vain a series of the measures used in like cases, this one resulted in a cure.

The animal was a fine, large hound of four years, which gave from eighty to one hundred and ten centilitres of milk daily. About the middle of the second month a notable improvement became manifest in the condition of the bones and muscular movements. At the commencement of the third month the child began to walk; at the hundredth day its health was good, the curvatures having nearly disappeared, and the child walked without aid. This result is easily explained by the comparative analysis of the human milk and the milk of the dog. Thus, according to the analyses of M. Jacquéme, the human milk contains only in 1,000 parts, 26.66 of butter, 39.26 of casein and extractive matter, and 1.38 of salts; while that of the dog has 97.20 parts per thousand of butter, 117 of casein, and 13.50 of salts.

APOLLINARIS WATER.—This water is the product of a spring in the valley of the Ahr, not far from the Rhine, and has qualities intermediate between those of the Seltersbrunnen, of Nassau, and the Krähnechen at Ems. It is, perhaps, the best natural mineral water for table purposes, and far exceeds the ordinary manufactured aerated waters, especially in this respect—that after withdrawing a portion of the contents of a bottle, it may be corked and set aside for even twenty-four hours, after which it will be found brisk as ever, instead of being flat and rapid, like ordinary Seltzer. Apollinaris water contains a considerable proportion of sodium salts, mainly carbonate, chloride, and sulphate, and will from these be found to act much in the same way as Ems water does in catarrhal affections of mucous membranes, for which that water is so renowned. But speaking merely from a lower standpoint, Apollinaris water is likely to take a high rank as a beverage.

TREATMENT OF CEREBRO-SPINAL MENINGITIS.—Dr. Dowse, of the Central London Sick Asylum, after giving a good account of the etiology, symptoms, and post-mortem appearances of this disease, as it affects the base of the brain, observes that there is no disease requiring more constant watching or careful medical interference than this. He has seen an acute meningitis and myelitis treated with those drugs which produce congestion; for instance, opium and strychnine. Nothing can be more productive of harm than such treatment in the first or acute stage.

1. It has to be considered how to relieve the vessels of the cord, and to equalize the action of the vasomotor system of nerves. Nothing appears to be of greater service in effecting this than the ergot of rye, and belladonna. The former he has prescribed in decided doses, such as half a drachm of the powder every four hours; and the latter he has applied to the spine in the form of a belladonna paste, made by mixing the extract with one-third its weight of glycerine.

2. To check the reflex vomiting, small pieces of ice must be swallowed, not sucked, as the full effect of

its sedative influence upon the stomach is thus obtained.

3. To relieve constipation, Dr. Dowse prefers the administration of a pill of the watery extract of aloes, for the reason that it acts upon the mucous membrane of the rectum and dilates the hemorrhoidal veins.

4. To relieve sleeplessness, both chloral and bromide of potassium have proved ineffectual, but what he found of most service was a suppository of eight grains of the extract of henbane, with four grains of the extract of conium.

5. One essential practical point must not be forgotten—namely, to keep the paralyzed bladder constantly free from urine. It is not sufficient to draw off the water night and morning, which is the course usually adopted, but a self-retaining catheter must be kept continually in the viscus.

6. In reference to diet, it ought to be both nutritive and stimulant from the first.

7. There is a stage in the treatment of this disease where quinine in large doses becomes of the most signal value—at that crisis when exhaustion appears imminent; the skin covered with sweat; temperature 102° to 105° ; pulse small, weak, and over 120. But more especially is quinine invaluable when rigors supervene, when it never fails to have a good effect. It must, however, be given in ten or twenty grain doses; and, if the stomach cannot tolerate it, must be introduced into the system by the rectum.

8. The abstraction of blood in any manner is not advisable.—*Med. Times and Gaz.*

VALUE OF THE STAINING PROCESS IN THE HISTOLOGY OF THE MORBID BRAIN.—Herbert C. Major, M.B., calls attention to a fact which he considers of deep interest and of real scientific value, viz., the fact that morbid and healthy tissues are affected by the logwood staining-fluid in different degrees within a corresponding period of time, and urges that the utility of staining should not be limited to the definition of cells, and the tracing out of their connections, but that it should constitute, in some sense, a test for the cerebral substance, and thus play no insignificant part in the detection of pathological change. He refers to the apparent difference between sections from the brain of a case of acute mania and one of senile atrophy. In the former the gray cortical layer was deeply stained and accurately defined from the internal white substance, which was hardly colored. In the latter the reverse was the case, the cortical layer being darkest in coloring and well defined.—*The Lancet*, Mar. 7.

CEDEMA OF THE LEFT UPPER EXTREMITY IN HEART-DISEASE.—M. Hanot draws attention to a fact which he has established in several instances of disease of the cardiac valves inducing general anasarca, and one which may be deserving of attention from clinical observers; viz., the earlier and more rapid development, and greater extent and persistency of edema of the left upper extremity, than of the right in these cases. He suggests, in explanation, the difference existing between the brachio-cephalic veins of the two sides; the longer and more oblique course on that of the left side causing, even in the normal state, a greater impediment to the return to the heart of the blood from the left than from the right arm.—*Gaz. Med. de Paris*.

USE OF GLAZIER'S PUTTY IN SURGERY.—Ordinary putty has been found by M. Conwall to be the softest and most applicable means of treating excrescences of tumors of various kind where compression is desirable, as it moulds itself so neatly to the surface. He thinks it to be superior to dextrine, silicate of soda, or plaster bandages.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, June 1, 1874.

RELATIONS OF AGE TO WORK.

In a pamphlet on the legal responsibilities of old age, by Dr. George M. Beard, of this city, there are many interesting facts presented, particularly those bearing upon the relation of age to mental work. The statements in regard to this latter are based upon a very extensive study of the lives of the representative thinkers and workers of history, and are as interesting and suggestive to our profession as to any other class who live by their brains. The author maintains that most of the original work of the world has been accomplished before the age of forty-five, and notably between thirty and forty.

Although the paper does not present us with such an array of statistical facts as would tend to convince the sceptical, still there is doubtless enough of soundness in the conclusions to claim the general attention. The examples which are brought forward are numerous and striking, and of themselves form an interesting and suggestive feature of the brochure. Any one who has not directed his attention specially to the subject will at first be startled with many of the assertions of the writer, and in the event of accepting the conclusions as a law, he becomes painfully aware that there is very little time left for making a reputation. There are, however, a great many circumstances, if for the sake of the argument we accept the conclusions, which must militate against the absolutism of the law which our author attempts to establish,—circumstances which especially apply to scientific work. Generally speaking, brilliant discoveries in science cannot be made by very young men. The very preparation in the shape of study and research which makes these discoveries possible, requires of itself a long period, and in case a young man is successful, it is generally more a matter of chance than anything else. In general literature, art, or generalship, early success is not so impossible, for the reason that there is not a propor-

tionate amount of study and preliminary preparation required. The very enthusiasm of youth, and the proverbial recklessness attending it, gives a peculiar and refreshing piquancy to the effusions of the young writer, a boldness of touch to the pencil of the young artist, or the requisite dash and daring to the exploits of the youthful commander. All these are elements which have a particular appreciation in the popular heart, and appeal in a peculiarly forcible manner to popular taste. A special genius for any of these pursuits may show itself early, and be entirely independent of any special culture, untrammelled by the dicta of any authority, or unschooled by the experience of those who have gone before. This assumption by no means proves that these talents may not be of a high order, only that their successful exercise does not necessitate a very long and thorough mental preparation for them. With the man of science, ambitious of making his mark, most of the so-called golden period of mental activity must be passed in severe training, while the same amount of brain-force is being spent by his brother in literature and art in founding a reputation.

While speaking of the sciences, we can take medicine as an example. Although we must admit that original work can be done, and is done, before the age of forty, we must also admit that a vast number of medical men do their best when they are past fifty. The very nature of the study of disease begets an enthusiasm for the work which extends in the well-educated man far into the hoary-headed period. Every medical man can call to mind striking examples of the truth of this assumption. We know of not a few who have made valuable discoveries when hard on to sixty, and, as far as we have been able of our personal knowledge to compare their number with younger men who have made equally valuable discoveries, we are not willing to admit that the latter are much in the majority. We believe that this is the common experience of every one who has any extended association with medical men. There is good reason for supposing that many of our older medical men would do more original work if the fitting opportunities for its performance were granted. We may make all due allowance for a decline of enthusiasm, but it strikes us a much greater impediment to special and original research is to be found in the overwhelming labor of a large practice, and the willing sacrifice of time which old-established practitioners make to it.

The writer of this pamphlet makes a statement that the golden period of mental activity is reached when the enthusiasm of youth is properly balanced by the experience of age. In medicine, as in all other sciences founded on recorded experience, is it not fair to assume that the time for original investigation must be late? Experience in medicine means a great deal, and unless this be considerable, enthusiasm cannot ac-

comply much, as the very foundation upon which it must work is wanting. How many a medical strippling has imagined he has made a discovery, and when he thinks he has perfected it, finds that the same idea had been brought out a century or two before. In the matter of personal experience, we can afford an example of what the enthusiasm of youth can accomplish in original research and what real scientific value can be attached to it without experience, or, what amounts to the same thing, without a knowledge of what was known before.

At the very commencement of our study of medicine, this enthusiasm led us towards what might be considered original brain-work. We resolved upon performing an operation upon a cat, and for this purpose administered chloroform to the animal. As the result of our unskilful management of the anæsthetic, the respiration of our patient became rather suddenly suspended, and the chagrin of the would-be operator was only equalled by the surprise of the spectators. Happening at the instant to place one hand upon the chest wall, and feeling the heart beat, we resolved to change the character of the operation and at the same time run the chance of seeing the heart beat for ourselves. The chest cavity was at once opened, and original thought brought its reward by the exhibition of the beating of the exposed heart. Desiring to prolong this exhibition, another thought occurred to us to keep the lungs in action. Our slight knowledge of anatomy was sufficient to enable us to find the trachea of the animal, sever its connections and expose it, and another original thought settled the question of inflation, which was carried on by the mouth through a dissecting blow-pipe. If the heart of an animal had never been exposed before and seen to beat, we might have made a discovery, but still the originality of the procedure was all the same. Many of our readers have doubtless had a similar experience in another direction before their enthusiasm was properly balanced by the weightier matters of written law. We have all doubtless missed the opportunity of being great discoverers because we have had the misfortune of being born after these discoveries have been made by some one else. If we assume that it is necessary to have a certain preparation for original work, and if before this preparation is complete a certain period of so-called fruitful brain activity must be passed, we must either assume that original discovery in medicine is next to an impossibility, or we must content ourselves in being mere copyists. If a young medical man has an original thought, and finds that by some unforeseen accident the same thought has not occurred to some one else, there may be a chance of turning his original thought to some personal account, and he may thus bridge over a good deal of hard study of the experience of others, and make a short-cut to a reputation; but this is mere good fortune, and an exception to the rule of scientific fame.

Although we believe that the golden age for medical discovery should be lengthened, we do not enter any special plea for old age. Beyond a certain time the brain is incapable of the requisite power for such work,—a time when all progress ceases, all capacity for original or any other kind of mental work is gone, when conservatism dwindles into old-fogyism, and when there is nothing left but the grinning skeleton of a dead reputation. When this period is reached, the old man should accept the issue, and gracefully yield the field to his more active junior.

THE AMERICAN MEDICAL ASSOCIATION.

THE American Medical Association meets this year, June 2, in Detroit, and, judging from the efforts made by the Committee of Arrangements, we have much to expect in the way of a scientific success. We have spoken so fully on many points connected with improvements to be wrought in organization, that it is unnecessary to refer to them further, at this time. There is certainly a promise of radical reform in many parts of its management, the realization of which will give us hope for even better things. The friends of the Association have, in such a light at least, no small interest in the success of the next meeting. All we have to wish for is, that the attendance will be good.

THE EDUCATION OF THE PEOPLE.

We have been pleased to notice the interest taken in matters of medical import which have been recently presented to the attention of the Social Congress by the members of our profession. The paper on School Hygiene, by Dr. A. L. Carroll, of New York, and the one on the Utility of T Hospitals, by J. Foster Jenkins, of Yonkers, are thoroughly representative of the advanced views of authorities on the subject, and deserve a special reference. It is also a subject for congratulation that the secular press has striven to do its part in giving the general public an opportunity of being informed upon these and kindred subjects. We have always contended that medical men were the proper teachers of the people on medical subjects, and this is one of the means to that end.

Reviews and Notices of Books.

THE PUERPERAL DISEASES. CLINICAL LECTURES DELIVERED AT BELLEVUE HOSPITAL. By FORDYCE BARKER, M.D., Clinical Professor of Midwifery and the Diseases of Women, Bellevue Hospital Med. Coll., etc. New York: D. Appleton & Co. 1874. Svo, pp. 512.

THIS valuable and interesting work possesses the double merit of filling a vacancy in English medical literature, and of comprising the latest established doctrines and facts in the pathology and therapeutics of the diseases of which it treats. It is a safe and reliable guide for the young practitioner, and cannot fail to interest and instruct the more experienced. It is composed of twenty clinical lectures, illustrated by the

reports of well-selected cases. The author's remarks on the use of ergot for relieving retention of urine "when due to loss of contractility of the muscular tissue of the bladder," and for preventing post-partum hemorrhage and after-pains, we can fully endorse, having for many years successfully used it for that purpose.

The first four lectures cannot be too strongly commended to the attention, not only of the inexperienced, but all general practitioners, believing as we do, that if the suggestions in these lectures were generally recognized and enforced, much danger and suffering might be avoided, and the mortality of the puerperal state greatly diminished. The value of the following therapeutical agents, which are mentioned in the first two lectures, and repeatedly referred to in the course of the work, viz.: opium, turpentine, carbolic acid, quinia and iron, can hardly be over-estimated.

The timely and judicious use of these remedies is generally successful in warding off many of the puerperal diseases, or of bringing them to a safe termination. The lecture on lacerations of the perineum is devoted principally to the prevention of such accidents, by the proper management of that organ during labor.

In the lecture on albuminuria, the author shows conclusively that it does not necessarily imply renal lesions; that it may "exist in its fullest development without causing convulsions; that dangerous and fatal convulsions may occur when albuminuria is wholly absent; that the nervous perturbations which cause the convulsions, . . . or even the convulsions themselves may be the cause of albuminuria," and that "albuminuria and uræmia are not identical terms, as either condition may exist and the other be absent." The treatment of albuminuria is considered in reference to the three periods in which it may occur, viz., pregnancy, parturition, and the puerperal state.

Two lectures are devoted to the consideration of puerperal convulsions; and the phenomena, causes, pathology and treatment of this disease receive all the attention that its importance demands. The "cure of anæmia," and "the relief of local congestions" are urged as prophylactic measures.

In the treatment of eclampsia, venesection, active purgatives, chloroform, and morphia are enumerated as the principal remedies. From our own experience it is gratifying to notice the importance the author attaches to bleeding. He says: "The bleeding is sedative to nervous irritation; it removes the tension from the brain, and protects it from the injury which might otherwise result from the convulsions; it relieves congestion of the kidneys and lungs, and takes off the pressure from the laboring heart; and it may be that it supplements the action of the kidneys, and removes from the blood a portion of its excess of uræa." In the lecture on lactation, Dr. Barker maintains that, with proper management, "milk-fever is an exceptional incident to the puerperal state." In proof of this, he refers to the reports of fifty-two cases, from the records of Bellevue Hospital, in only four of which were there "any symptoms, either of increased frequency of the pulse, or a rise in the temperature indicating milk-fever."

That portion of the lecture devoted to the treatment of the various affections of the nipple is of especial value to the young practitioner, as it contains the only explicit and practical instructions for their management we have yet seen published. Prof. Barker theorizes ingeniously on the pathology of phlegmasia dolens, rejecting the commonly received doctrine of crural phlebitis as being the cause of phlegmasia, claiming that either may exist in the absence of the other, and pertinently remarks:

(1.) "That the assigned cause or condition should always be present when the disease exists.

(2.) "That the disease should always exist when the assigned cause is present in its full development;" and adds, "I think all theories of disease should be brought to the rigid test of such a standard." He objects, also, to the doctrines of Simpson and others, and concludes the discussion by declaring that "we are still as ignorant of its real pathological nature as we are of rheumatism and many other diseases."

Of the treatment of this disease the author justly remarks that "it will be judicious and successful just in proportion as it is free from all bias from theoretical speculations as to the pathological nature of the affection, and just in proportion as it is based on a sound and just appreciation of the special indications of the case."

A lecture is devoted to puerperal septicæmia and pyæmia, in which the distinctions between the two affections are clearly defined; and two lectures to puerperal fever, which the author believes to be "a fever peculiar to puerperal women, . . . that its symptoms . . . are essential and are not in consequence of any local lesions, and it is as much a distinct disease as typhus fever, typhoid fever, or relapsing fever." He mentions two facts, which he thinks are sufficient to establish the distinction between puerperal fever and septicæmia, viz.: 1st. "It has often occurred that one physician is tracked by puerperal fever, following a series of labors, while in the same neighborhood, village, or city the disease is not met with in the practice of any other physician." 2. That he has been "unable to find that a single instance has yet been published where septicæmia has tracked the practice of one surgeon in any city or village, while the other surgeons in the same neighborhood did not meet with this affection." In the treatment of these diseases Prof. Barker claims that veratrum viride is contraindicated in septicæmia, while it is especially valuable as a sedative in puerperal fever. Quinia is justly extolled as an anti-pyretic and anti-pyrogenic in these diseases. We regret that time and space forbid a more extended notice of a work so replete with sound pathological views and practical clinical instruction.

CLINICAL NOTES ON THE ELECTRIC CAUTERY IN UTERINE SURGERY. By J. BYRNE, M.D., M.R.C.S.E. Pp. 68. William Wood & Co. 1873.

Dr. BYRNE, in sixty-eight pages, has given a valuable exposition of the application of the electric cautery to uterine surgery. The book is handsomely gotten up, and abounds in illustrations. A concise history of the introduction of this agent into surgery is given, and the ingenuity of the author is manifested in the original apparatus that he has devised, including the battery, which it strikes us is by far the best, in cost, simplicity, and action, that has yet been suggested. Under his own observation seventy-two cautery operations have been performed, and he records the clinical histories of the most interesting of these, besides giving the general results. These include cases of epithelioma, encephaloid, or medullary cancer; catarrhal, inflammatory, and ulcerative affections of cervical canal; amputation of cervix (non-malignant); fibrous and fibro-cellular polypi; sessile fibroid tumors; deep ulceration of os and cervix; intra-uterine vegetations (non-malignant), and vascular tumors of urethra. The results of the operations recorded are exceedingly satisfactory, and must aid in stimulating the more common use of the cautery. The conclusions which are deduced are honest and unprejudiced; and in the sparsity of our literature on this subject, this little book must find a place in many professional libraries.

GALVANO-THERAPEUTICS. A Revised Reprint of a Report made to the Illinois State Medical Society. 1873. Lindsay & Blakiston.

The author of this report does not present a comprehensive exposition of the theory and applications of galvanism to the treatment of disease, but gives the results obtained by him in practice. An effort is made to formulate the indications for the use of galvanism, and several theories as to the mode of action of the current are advanced. The evidences and want of elaboration that are manifest in this part of the book render the clinical contributions the only valuable portion. The book is written in a style awkward and constrained, so that at times it is difficult to appreciate the author's ideas. As a clinical contribution, however, it is welcome, for in no department of therapeutics are numerous clinical observations so much needed as in electrology. It is impossible as yet to formulate the laws and indications for the application of electricity, and the limits of its action have not yet been definitely defined; so that until a mass of clinical observations, made by competent and honest observers, shall have been reported, it will be impossible to form deductions that will allow of a systematic and intelligent use of this agent.

ARTICLES IN OUR EXCHANGES.

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

Cod-liver oil. KIRCHNER. *Berl. Klin. Woch.*, 1, 1874.
The hydrate of chloral and its employment in medicine. LIEBREICH. *Berl. Klin. Woch.*, 5, 1874.

Reports of Hospitals.

THE TREATMENT OF CONSUMPTION.

GLEANED FROM CLINICAL LECTURES AT THE HOSPITALS OF NEW YORK.

THE great controlling idea which should govern the medical adviser in the management of this class of cases is the adoption of such measures as will secure the best possible condition of nutrition.

As far as the lungs are concerned, they should be made of secondary consideration. Special symptoms

and local manifestations are not to be regarded as the great questions at issue. Not everything that is done is to be done with the view of checking a diarrhoea, improving the appetite, arresting night-sweats, quieting the cough, etc.

THE QUESTION OF CLIMATE IN PHTHISIS.

First, a proper atmosphere should be given the patient to live in. An air should be obtained, if possible, of such a nature that it can be breathed for the greater part of the twenty-four hours. Second, give the patient the benefit of sunlight. Third, avoid an atmosphere loaded with dust. Fourth, exercise without producing fatigue.

The climate should be selected, if change of climate is to be made, in which the patient can be the most comfortable for the greater part of the twenty-four hours, for that is the climate which is to prove the most beneficial. The temperature and locality are in general secondary considerations. As a rule, a low and damp location is injurious.

If the patient cannot be exposed to out-door air without feeling chilled, and is necessitated to sit by a fire when he returns, for the sake of again feeling comfortable, it is much better for him to remain in the house and make an atmosphere for himself by artificial means, and then take regularly such light gymnastic exercise as will keep the body in the best possible condition. If change of location is to be made, the patient should be sent to some place where he will have a good time. Never send a patient where he will be surrounded with depressing and unhappy influences. Never send a patient in the advanced stage of consumption away from home, unless he is so situated that he can take his home and all its comforts with him. Never send a person with consumption to the sea-shore, unless the experience of the individual has proved such an atmosphere beneficial. In general it does harm. Some favor long sea-voyages in the earliest stages. Especially avoid the habit of sending every patient to the same place. In case the patient enjoys hunting and fishing, if he can be sent to a locality where he can have his favorite sports, it will prove an additional item in his favor. The man who is fond of these sports is much more likely to get well of his phthisis. If these external general conditions can be controlled, no great amount of anxiety, as a rule, need be manifested with regard to the cough. It is the cough generally that most attracts the attention of the patient. The great object to be held in view is to raise the health of the patient to a level above that in which phthisis progresses. The power of drugs to accomplish this is very doubtful. Alcohol is of doubtful efficacy. If used at all, it should be used with the view of assisting digestion; and the article selected should be that most agreeable to the stomach. Air free from moisture and dust, food and exercise, are the things to be relied upon in the general treatment of this disease.

There are certain effects of the disease which the physician will be called upon to counteract, and for the relief of these he may be obliged to resort to some therapeutical measures. It is to these conditions and measures that attention is now especially directed.

THE COUGH OF PHTHISIS.

Phthisis occasionally occurs without cough, but these cases are almost always complicated ones. The insane may go through the entire course of phthisis without cough. For the relief of the cough of consumption an almost endless retinue of cough mixtures have been formulated. Most of them contain opium. The effect of the opium is simply to blunt the sensibility, and

permit the material to accumulate which is to be expectorated. An additional result is, that opium is almost sure to injure the patient's digestion.

If it becomes necessary to do anything for the relief of cough, there is nothing more serviceable than morphine. While administering it, do as little as possible in the way of producing another evil, by the arrest of one already existing.

What are commonly known as cough mixtures are ignored. When remedies for relieving the cough must be used, use, by preference, those which have the most powerful quieting influence without disturbing the stomach.

DISTRESS AFTER EATING, AND DIARRHŒA.

This is a very common occurrence. There are two conditions upon which diarrhoea and distress after eating depend. They may depend upon a hyperæmic condition of the gastro-intestinal mucous membrane, consequent upon irritation produced by indigestible food, or diarrhoea may be caused by ulceration of the intestines. When diarrhoea or distress after eating occurs in the earlier stages of the disease, it is most probably due to hyperæsthetic condition of the mucous membrane, and a hyperæmic condition, of which the diarrhoea is but an effort to relieve the engorged mucous membrane. Simply arresting the discharges from the bowels is not well. Produce several watery discharges without pain, and the engorgement will be relieved; and then opium and astringents may be used with benefit if necessary. As a rule, opiates and astringents are to be resorted to only as secondary measures.

A very efficient prescription to be administered under these circumstances is:—

R. Sulphate of magnesia.

Tr. opii camph. ʒi.

Aqua. Oj.

M.

S. Wineglassful every two or three hours, until two or three free watery stools are produced. To prevent recurrence, regulate the diet. When the bowels are irritable, beef-tea is apt to purge. Milk, farinaceous food, yolks of fresh eggs beaten up with wine and sugar. If these do not agree with the patient, raw beef scraped fine may be tried; or it may be just heated through, and then scraped fine and seasoned with pepper and salt; and in some hospitals vinegar is also allowed.

An exceedingly serviceable remedy to be regularly administered in these cases of disturbed digestion, irritable mucous membrane and diarrhoea, is *lacto-phosphate of lime*. The article must be fresh, and must be kept in a cool place. Unless these precautions are taken, the remedy itself will prove purgative.

Pepsin combined with *muricic acid* is an excellent assistant to digestion under these circumstances; fatty meat, thoroughly boiled pork, fresh butter; perhaps cod-liver oil.

Thoroughly boiled pork is most excellent for children who suffer from summer complaint. The diarrhoea of phthisis may occur from simple thickening of the mucous membrane of the small intestines. When the diarrhoea depends upon ulcerations in the intestines, the regulation of the diet is an exceedingly troublesome undertaking. Resort should be had to those articles of diet which will give as little trouble as possible in the latter stages of the digestive process. If the ulceration is in the small intestines, cod-liver oil and the hypophosphites may be of great service. If the ulceration is in the large intestines, but little more than temporary relief can be expected. The presence

of blood in the discharges is regarded as evidence of ulcerations in the intestines. The seat of the pain, tenesmus, etc., is generally sufficient to distinguish ulceration of the large intestines from ulceration of the small intestines.

The most relief to be obtained from *drugs* is when the diarrhoea depends upon ulceration of the small intestines. The treatment adopted for the diarrhoea which depends upon a condition of hyperemia is not of much service in this condition.

Among drugs sub-carbonate of bismuth is regarded as one of the best remedies that can be employed. It may be given in doses as high as ʒ i. t. i. d.

R. Bismuth subnitrat. ʒ i.

Morphine sulph. gr. i.

M.

Div. in pulv. No. xij.

S. One every four, six, or eight hours, p. r. n.

Sometimes benefit will be derived from the use of mineral waters. Water from the Rock Ridge linc-spring of Virginia is the *best* that can be employed. The water contains lime and iron, and is astringent and tonic. Of this ʒ ij. to ʒ iv. may be taken every three to six hours. It can be taken clear or with other water.

Oak Orchard water is regarded as very serviceable in the treatment of chronic enteric difficulties of any kind.

In the latter stages of the diarrhoea of phthisis, especially when the large intestines are the seat of ulcerations, *opium* is the chief remedy to be relied upon. When given to relieve pain, hypodermically or by suppositories, it is much less liable to disturb the stomach. Suppositories made of *gum opium* alone are much more efficient than when the opium is compounded with other substances.

Salicine, in ten-grain doses t. i. d., has something of a reputation in the treatment of diarrhoea of phthisis. The remedy may be given in divided doses, and administered more frequently if desirable.

VOMITING AFTER MEALS.

This symptom is quite common, and when present is apt to be troublesome. A wineglass of champagne, taken during meals, will sometimes arrest it at once.
